In regions affected by iodine deficiency, the most cost-effective and sustainable method to control iodine deficiency is through salt iodization.[17] Salt iodization is the recommended strategy for control of iodine deficiency disorders, because salt is one of few foodstuffs consumed by virtually everyone, and salt intake is fairly consistent through the year. The addition of iodine to salt does not affect its color or taste. In many countries, salt production/importation is limited to a few sources, and iodization technology is simple and inexpensive. Finally, the quantity of iodine in salt can be simply and inexpensively monitored at the production, retail, and household levels.[17]

Iodine can be added to salt in the form of KI or potassium iodate (KIO_3). Because KIO_3 has better stability than KI in the presence of salt impurities, humidity, and poor packaging,[69,70] it is the recommended form in tropical countries with low-grade salt. Potassium iodate has been granted "generally recognized as safe" status by the US Food and Drug Administration and has been used for decades as an additive to salt and bread.[71] Salt iodization is cost-effective.[72,73] Worldwide, the annual costs of salt iodization are US $0.02 to 0.05 per child covered, and the costs per disability-adjusted life years (DALYs) gained are US $34 to 36.[74]

The original concept of salt iodization was for it to be universal; that is, the iodization of all edible salt used in households and food processing.[17] However, many national programs have focused mainly on only household salt being iodized. The consumption of salt through processed foods is increasing in many countries, and in many middle- and high-income countries most salt is consumed through processed foods.[75] If the salt in such foods is well iodized, it can be an important source of iodine.[76] National salt iodization programs should encourage and monitor the use of iodized salt in processed foods. Iodine coming from processed foods likely explains why, in some countries, the mUIC indicates adequate iodine intakes despite low coverage of households with iodized salt.[77] There is growing worldwide interest in reducing salt intake to prevent hypertension and other noncommunicable diseases. Concerns have been raised that programs to reduce dietary salt could adversely impact programs to prevent iodine deficiency, and, conversely, that iodizing salt could encourage higher salt intakes.[78] The WHO has emphasized that these programs are compatible but need to be carefully aligned.[67] Both programs have common elements, including program monitoring via urine collections and interactions with the food and salt industries; this provides an opportunity to share and leverage resources and approaches to be more effective and efficient.[67,78] As salt intakes fall, iodine levels can be increased in salt to adjust for the recommended reduction in dietary salt to less than 5 g/day.[78]

Iodine Supplementation

In some areas, iodization of salt may not be practical for control of iodine deficiency, and iodine supplements can be given.[17] Iodized oil supplements are prepared by esterification of the unsaturated fatty

TABLE 76.3 Recommendations for Iodine Supplementation in Pregnancy and Infancy in Areas Where <90% of Households are Using Iodized Salt and the Median Urinary Iodine Concentration is <100 μg/L in Schoolchildren

Women of child-bearing age	A single annual oral dose of 400 mg of iodine as iodized oil OR A daily oral dose of iodine as potassium iodide should be given so that the total iodine intake meets the RNI of 150 μg/d of iodine
Women who are pregnant or lactating	A single annual oral dose of 400 mg of iodine as iodized oil OR A daily oral dose of iodine as potassium iodide should be given so that the total iodine intake meets the RNI of 250 μg/d iodine. Iodized oil should not be given to a woman who has already been given iodized oil during her current pregnancy or up to 3 mo before her current pregnancy started
Children aged 0–6 mo	A single oral dose of 100 mg of iodine as iodized oil OR A daily oral dose of iodine as potassium iodide should be given so that the total iodine intake meets the of 90 μg/d of iodine Should be given iodized oil only if the mother was not supplemented during pregnancy or if the child is not being breastfed
Children aged 7–24 mo	A single annual oral dose of 200 mg of iodine as iodized oil as soon as possible after reaching 7 mo of age OR A daily oral dose of iodine as potassium iodide should be given so that the total iodine intake meets the RNI of 90 μg/d of iodine

RNI, Recommended nutrient intake.

(From WHO Secretariat, Andersson M, de Benoist B, et al. Prevention and control of iodine deficiency in pregnant and lactating women and in children less than 2-years-old: conclusions and recommendations of the Technical Consultation. *Public Health Nutr.* 2007;10:1606–1611.)

TABLE 76.4 Recommended Safe Upper Intake Levels for Iodine

Age Group	IOM (μg/day)[7]	SCF (μg/day)[136]	WHO (μg/kg/day)[137,138]
Premature infants	ND	ND	100
0–6 months	ND	ND	150
7–12 months	ND	ND	140
1–3 years	200	200	50
4–6 years	300 (4–8 years)	250	
7–10 years	600 (9–13 years)	300	50 (7–12 years)
11–14 years		450	30 (>13 years)
15–17 years	900 (14–18 years)	500	
Adults	1100	600	
Pregnant and lactating women	1100	600	40

IOM, United States Institute of Medicine; *SCF*, European Union Scientific Committee on Foods; *WHO*, World Health Organization; *ND*, not determined.

acids in seed or vegetable oils and addition of iodine to the double bonds.[79] It can be given orally or by intramuscular injection[17,80]; usual doses are 200 to 400 mg iodine/year.[17] Iodine can also be given as KI or KIO$_3$ as drops or tablets. Single oral doses of potassium iodide monthly (30 mg) or biweekly (8 mg) can provide adequate iodine for school-age children.[81] In iodine-deficient regions with weak iodized salt distribution, the WHO recommends that supplements be given to pregnant women, lactating women, and infants, according to the strategy shown in Table 76.3.[82] Lactating women who receive one dose of 400 mg iodine as oral iodized oil soon after delivery can provide adequate iodine to their infants through breast milk for at least 6 months.[83]

KEY POINTS

- In areas where iodized salt does not provide sufficient iodine, oral iodine supplementation can be given, either as long-lasting iodized oil or as daily iodine supplements.

IODINE EXCESS

In animals and humans, the thyroid gland has intrinsic autoregulatory mechanisms to effectively adjust to excess iodide intake.[9] The acute, transient inhibitory effect of iodide excess on thyroid iodide organification is termed the acute Wolff–Chaikoff effect, and it appears that adaptation to or escape from the Wolff–Chaikoff effect is due to a decrease in NIS protein,[84] thereby lowering intrathyroidal iodide and allowing normal hormone synthesis to resume. Since the initial description by Coindet in 1821 and the subsequent definition by Breuer and Kocher in 1904, iodide-induced thyrotoxicosis has been reported in patients with a variety of underlying thyroid diseases. Hyperthyroidism after iodine administration is termed the Jod–Basedow effect, which is named for the German word for iodine, "jod," and the name of Karl Adolph von Basedow, a German physician who described the effect.[85] Iodine-induced thyrotoxicosis may occur in patients with iodide-deficiency goiter, in patients with multinodular goiters who reside in areas of iodide sufficiency or deficiency, in various thyroid disorders, and in people with no evidence of underlying thyroid disease.[85,86] The incidence of iodine-induced thyrotoxicosis during the introduction of salt iodization in areas previously iodide deficient is variable, but is usually predicted by the severity of iodine deficiency before prophylaxis and to the increase in iodine intake.[87] In Zimbabwe, following the introduction of iodized salt at 30 to 90 mg iodine/kg, there was a 3-fold increase in thyrotoxicosis.[88] Thyrotoxicosis occurs when iodide repletion permits the autonomous thyroid tissue to synthesize and release excess quantities of thyroid hormone. In Denmark, in a population with moderate iodide deficiency, the prevalence of thyrotoxicosis slightly increased after iodine intake was increased by only 50 μg/day[89]; most patients had multinodular goiters and were elderly. This increase led to a transient increase in therapeutic use of antithyroid drugs in the population, which fell to a rate lower than before salt iodization after about 10 years.[90]

The lowest observed adverse effect level (LOAEL) proposed for iodine intakes is 1700 to 1800 μg/day. The tolerable upper intake level (UL) for iodine is the highest average daily intake that is likely to pose no risk of adverse health effects in the general population[5] (Table 76.4). The United States Institute of Medicine recommends a UL of 1100 μg/day,[5] whereas the European Union Scientific Committee on Foods recommends a UL of 600 μg/day[91]; these differences are due to differences in interpretation of the LOAEL effect. In 1988, the joint Food and Agriculture Organization of the United Nations and WHO Expert Committee on Food Additives suggested a UL from all iodine sources of 1 mg/day would be safe for most of the population.[92,93] For population monitoring of iodine excess, the WHO recommends using the mUIC; the upper threshold for iodine excess is a mUIC greater than or equal to 300 μg/L in 6- to 12-year-old children,[17,94] or greater than or equal to 500 μg/L in pregnant women.[17]

Though most foods are poor in native iodine, certain seaweeds, including kelp and kombu, are iodide-rich and can cause iodine excess.[95,96] Unprocessed meat is generally low in iodine, but accidental thyroid tissue found in ground beef has caused thyrotoxicosis (hamburger thyrotoxicosis).[97] Groundwater usually has an iodine content of only 1 to 10 μg/L, but iodine-rich drinking water is a source of excess iodide in some areas of China, where water has an iodine concentration of 300 to 500 μg/L.[98] Iodide readily crosses the placenta and is concentrated by the fetal thyroid. Large quantities of iodide administered to pregnant women may result in goiter in the newborn, probably because the fetal thyroid is highly sensitive to the inhibitory effect of iodide on hormone synthesis.[99] During lactation, iodide is also actively transported from the bloodstream into the breast and secreted into breast milk. Perinatal hypothyroidism and high infant urinary iodine levels were reported in newborns whose mothers consumed a large amount of seaweed during pregnancy and the postpartum period.[100]

KEY POINTS

- Both acute and chronic excess iodine intakes can have adverse effects on thyroid function.

BASIC ASPECTS

Definition and Clinical Manifestation

Benign nodular thyroid includes a heterogeneous spectrum of alterations that are highly prevalent in iodine-deficient areas. Very broadly, it can be divided into solitary nodular and multinodular thyroid disease. Histologically, benign thyroid nodules are distinguished by morphologic criteria according to the World Health Organization (WHO) classification as encapsulated lesions (true adenomas) or adenomatous nodules, which lack a capsule.[1] Functionally, nodules are classified as "cold," "normal," or "hot" depending on whether they show decreased, normal, or increased uptake, respectively, on scintigraphy. Approximately 50% to 85% of all nodules are "cold," up to 40% are scintigraphically indeterminate, and approximately 10% are "hot," although the relative frequencies will vary geographically as a function of iodine intake.

Clonal analysis of thyroid nodules indicates that most of them are "true" monoclonal neoplasias rather than polyclonal hyperplastic lesions. Strict histologic criteria for an adenoma and its differentiation from hyperplastic thyroid nodules or adenomatous nodules (without a capsule) are difficult. Therefore, distinction of hyperplastic thyroid nodules from neoplasias should, ideally, take into account their clonal composition.[1] Because many thyroid nodules without a capsule (adenomatous nodules) are monoclonal, a mixed functional and molecular definition of true thyroid tumors, as outlined in Fig. 77.1, appears more objective and consistent. In contrast to solitary nodular thyroid disease, which has a more uniform clinical, pathologic, and molecular picture, multinodular goiter (MNG) and toxic multinodular goiter (TMNG) are more complex entities. Functionally, they often include a mixture of hyper-, hypo-, or normally functioning thyroid lesions within the same gland. The overall balance of functional properties of individual thyroid nodules within a multinodular goiter ultimately determines the functional status in the individual patient, who may be euthyroid, be subclinically hyperthyroid, or have overt hyperthyroidism. The term MNG is applied in the first scenario, while TMNG refers to the latter situations. It is important to emphasize that this functional characterization is not stationary, and hyperthyroidism may develop over time, because patients with TMNG usually have a history of longstanding MNG.[2] In general, development of MNG proceeds in two phases: global activation of thyroid epithelial cell proliferation (e.g., as the result of iodine deficiency or other goitrogenic stimuli) leading to goiter formation, and a focal increase of thyroid epithelial cell proliferation causing thyroid nodules. So far, the most common stimulus for focal proliferation is a somatic mutation, as detailed in the following section.

Environment and Heredity

Historically, nontoxic goiter was mainly regarded as a consequence of iodine deficiency. However, a number of goitrogens and cigarette smoking are important environmental risk factors in the etiology of nontoxic goiter.[3] The impact of smoking, most likely mediated by thiocyanate, which can competitively inhibit iodide transport into the thyroid, has been extensively studied.[3] Additional important etiological factors include sex,[4] age,[5] and increased body mass index (BMI).[5] The effect of a certain goitrogen is influenced by the degree of iodine intake and varies regionally and interindividually. However, it is most likely

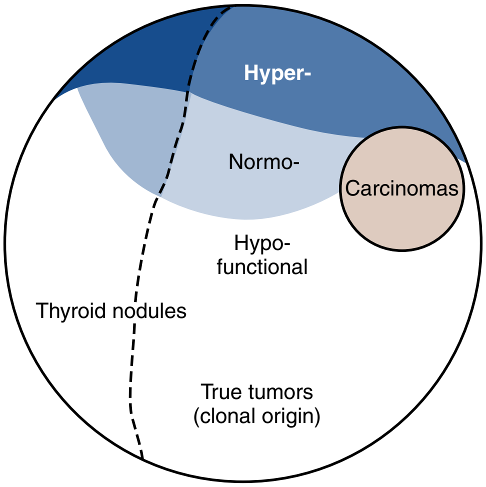

Fig. 77.1 Clonality, histologic, and scintigraphic classification of thyroid tumors, and their respective overlap. Clonality studies imply that the majority of thyroid nodules are "true" thyroid tumors. Polyclonal hyperplastic nodules lack a capsule and a growth pattern that is different from the surrounding normal parenchyma. The clonality and histologic characteristics of benign thyroid nodules overlap differentially with the scintigraphic characteristics, whereas primary thyroid carcinomas are mostly clonal tumors with mostly hypofunctional appearance on scintigraphy.

that interactions between environmental factors and individual genetic determinants ultimately determine goiter development.[5-7] Nontoxic goiter appearing early in life, often clustering in families, suggests strong genetic susceptibility, whereas the environmental determinants are more likely to have additive or triggering effects.

In contrast to sporadic goiters, most cases of familial goiter present an autosomal dominant pattern of inheritance, indicating an important genetic component.[7] Gene–gene interactions or various polygenic mechanisms (i.e., synergistic effects of several variants or polymorphisms) are likely to contribute to the complex pathogenesis of nontoxic goiter and also offer an explanation for its genetic heterogeneity. A strong genetic predisposition is indicated by family and twin studies. Children of parents with goiter have a significantly higher risk for developing goiter compared with children of nongoitrous parents. The high incidence in females and the higher concordance in monozygotic than in dizygotic twins also suggest a genetic predisposition. Moreover, there is preliminary evidence of a positive family history for thyroid diseases in those who have postoperative relapse of goiter, which can occur months to years after surgery.

The development of nontoxic goiter is most likely a continuous process that starts with thyroid hyperplasia. Therefore, defects in genes that play an important role in thyroid physiology and thyroid hormone synthesis could predispose to goiter development, especially in the case of borderline or overt iodine deficiency. Such defects may be associated with partial dyshormonogenesis and the hyperplasia, as well as the subsequent nodular transformation, may reflect an adaptive response to meet the requirements for hormone synthesis. Genes that encode proteins involved in thyroid hormone synthesis (sodium iodide symporter [*SLC5A5*], thyroblobuline [*TG*], thyroid peroxidase [*TPO*], Pendred syndrome gene [*SLC26A4*], solute carrier SLC26A7 [*SLC26A7*], iodotyrosine deiodinase [*DEHAL 1*], dual oxidase 2 and dual oxidase maturation factor [*DUOX2, DUOXA2*], thyroid-stimulating hormone [TSH] receptor [TSHR]) are convincing candidate genes in familial euthyroid goiter. Originally, several mutations in these genes were identified in patients with congenital hypothyroidism. However, in cases of less severe functional impairment, which can still be functionally compensated, a contribution of variants of these genes in the etiology of nontoxic goiter is possible. Moreover, individuals with biallelic mutations in the *TG* or *SLC26* gene can, for example, develop nontoxic goiters.

Linkage analyses have been performed to identify novel susceptibility loci to gain further insights into the genetic mechanisms that contribute to the etiology of nontoxic familial goiter. Linkage studies have identified several candidate loci (*MNG*, *MNG2*, 2q, 3p, 7q, and 8p). Remarkably, for the first time, a more prevalent putative risk locus, present in 20% of the families investigated, has been identified.[8] The recognition of genetic loci conferring susceptibility for goiter development, together with established environmental factors, indicates that nontoxic goiter can be defined as a complex multifactorial disease.

Whereas linkage studies are suitable for the detection of candidate genes with a strong effect, it is possible to miss weak genetic defects of first-line candidate gene variants or of novel genes, which are more likely detected by association studies. A genome-wide association study identified the *FGF7* and the *CAPZB* genes, which are involved in the regulation of thyroid epithelial cell proliferation and colloid engulfment during cellular uptake of thyroglobulin as susceptibility loci for goiter.[9] One to two percent of adult-onset thyroid nodules harbor a hotspot *DICER1* mutation, and three quarters of these mutations are accompanied by a second hit, presumably with loss of function in *DICER1*. Some of these loss of function variants are probably germline in origin, thus representing previously undiagnosed *DICER1* syndrome patients.[10] Importantly, it is conceivable that the sum of several low-penetrance alleles in different genomic regions could lead to goiter predisposition. Therefore, the widely accepted risk factors such as iodine deficiency, smoking, old age, and female sex are likely to interact with and/or trigger the genetic susceptibility. Further narrowing down the candidate regions and performing association studies with single nucleotide polymorphisms in additional families, especially in case-control association studies, and the confirmation of association study results in other populations are necessary to further corroborate the role of currently identified candidate genes for hereditary nontoxic goiter.

Molecular Mechanisms for Euthyroid, Cold, and Hot Thyroid Nodules

Most goiters become nodular with time. Thyroid nodules can present as solitary lesion or as multinodular thyroid or goiter. Functionally, they cover a wide spectrum from autonomous hyperfunctioning adenomas, so-called toxic adenomas (TAs), to nodules that have lost the ability to concentrate iodine, and hence, produce thyroid hormones. From animal models of hyperplasia caused by iodine depletion, it has become apparent that there is an increase in functional activity, as well as a tremendous increase in thyroid cell number. These two events may be associated with an increased rate of mutational events. Thyroid hormone synthesis requires the generation of hydrogen peroxide (H2O2), which may damage genomic DNA and cause mutations. Besides being important as an oxidizing agent for iodine during hormone synthesis, H2O2 can be a major source of free radicals and reactive oxygen species (ROS). Because these molecules can cause substantial damage to a cell and impair normal function, thyroid epithelial cells are likely to have a potent defense mechanism to counterbalance potential damage mediated by free radicals. It has been shown that antioxidant enzymes, such as glutathione peroxidases (GPXs) or thyroid peroxidase, are upregulated during thyroid hormone synthesis. GPX3 has also been suggested to directly interfere with thyroid hormone synthesis by affecting the concentration of H2O2. Together with a higher spontaneous mutation rate, a higher replication rate will more often prevent mutation repair and increase the mutation load of the thyroid, thereby randomly

Adaptation to iodine deficiency
Genetic susceptibility
Maladaptation to iodine deficiency

Fig. 77.2 Hypothesis for thyroid nodular transformation. The starting point for the development of multinodular goiter is hyperplasia induced by goitrogenic stimuli (e.g., iodine deficiency). Iodine deficiency increases mutagenesis directly (production of hydrogen peroxide/free radicals) or indirectly (proliferation and increased number of cell divisions). Subsequently, hyperplasia forms cell clones. Some of them contain somatic mutations of the thyroid-stimulating hormone receptor leading to autonomously functioning thyroid nodules *(red circles)* or contain mutations that lead to dedifferentiation and therefore cold thyroid nodules or cold adenomas *(blue circles)*.

affecting genes crucial for thyrocyte physiology. Mutations that confer a growth advantage (e.g., activating TSHR or Gsα mutations) very likely initiate focal growth. Hence, autonomously functioning thyroid nodules (AFTNs) are thought to develop from small cell clones that contain advantageous somatic mutations as shown for the TSHR in “hot” microscopic regions of euthyroid goiters.[11]

However, thyroid nodules also occur in thyroid glands of normal size. Interestingly, a recent study reported that the growth of established thyroid nodules is a process limited to the thyroid nodules, but not associated with growth of the surrounding nonnodular thyroid tissue.[12] This condition should be distinguished from nodular goiter and is better characterized as a uni- or multinodular thyroid gland.

Epidemiologic studies, animal models, and molecular/genetic data outline a general theory of nodular transformation. Based on the identification of somatic mutations and the predominant clonal origin of AFTNs and cold thyroid nodules, the following sequence of events could lead to thyroid nodular transformation in three steps, as outlined in Fig. 77.2.[5] First, iodine deficiency, nutritional goitrogens, or autoimmunity cause diffuse thyroid hyperplasia. Then, at this stage of thyroid hyperplasia, increased proliferation, together with possible DNA damage associated with H2O2 generation, causes a higher mutation load (i.e., a higher number of cells bearing mutations). Some of these spontaneous mutations confer constitutive activation of the cyclic adenosine monophosphate (cAMP) cascade (e.g., TSHR and Gsα mutations), which stimulates growth and function. Finally, in a proliferating thyroid, growth factor expression (e.g., insulin-like growth factor 1 [IGF-1], transforming growth factor β1 [TGF-β1], or epidermal growth factor [EGF]) is increased. As a result of growth factor costimulation, most cells divide and form small clones. After increased growth factor expression ceases, small clones with activating mutations will further proliferate if they maintain an intrinsic proliferative advantage. They can thus form small foci, which develop into thyroid nodules. This mechanism could explain AFTNs by advantageous mutations that both initiate growth and function of the affected thyroid cells, as well as cold thyroid nodules by mutations that stimulate proliferation only (e.g., RAS mutations or other mutations in the RAS/RAF/MEK/ERK/MAP cascade).

Because of the slow proliferation rate of thyroid epithelial cells, a long period (decades) between initiation of the neoplasia and appearance of MNG seems likely. Therefore, the prevalence of thyroid neoplasias can be potentially explained by a high frequency of tumor initiation and/or enhanced thyroid epithelial cell proliferation. The origin of tumor formation in the thyroid could therefore be induced by a high mutation rate and aberrant growth stimulation in the thyroid gland. The latter very likely involves endogenous growth factors and/or exogenous goitrogenic substances.

In addition to the generally high mutation rate in the normal thyroid gland, environmental and lifestyle factors could add to the pool of DNA damage and increase mutagenesis and tumor initiation. For example, smoking could lead to intracellular iodine deficiency through thiocyanate-induced blocking of the iodine transport into thyrocytes.[13]

As outlined earlier, H2O2-mediated ROS generation is very likely to be an important starting point for thyroid tumor development (Fig. 77.3). Because H2O2 is essential for the oxidation of iodide in thyroid hormone synthesis, changes in iodine concentration are associated with the cellular H2O2 concentrations. In fact, generation of H2O2 is inhibited by iodide *in vivo* and *in vitro*. Moreover, H2O2 generation is stimulated by higher concentrations of TSH (predominantly by the protein kinase C pathway rather than the protein kinase A pathway). Low iodine levels and markers of increased thyroid functionality suggest activation of H2O2 generation, which could result in DNA damage and somatic mutations. Low iodine and high H2O2 levels should therefore activate antioxidative defense, which should be detectable in the cellular regulation of enzymes involved in defense against oxidative stress.

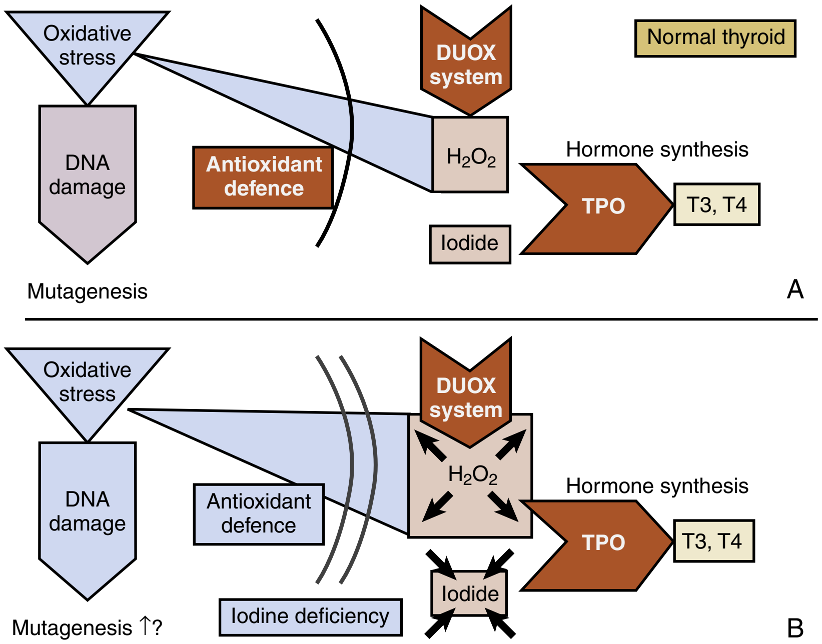

Fig. 77.3 Mechanisms that may cause mutagenesis in the thyroid gland. The figure shows the key molecules involved in those parts of thyroid hormone synthesis, which—in conditions of iodine and most likely also selenium deficiency—lead to oxidative stress, DNA damage, and possibly mutagenesis. **A,** In the normal thyroid gland, the enzymes DUOX1 and DUOX2 generate H2O2, and TPO transfers oxidized iodine to tyrosyl residues of thyroglobulin, the precursor for T3 and T4 synthesis. H2O2 is, however, a source of ROS, which—with other oxidative stress—can cause DNA damage. Normally, antioxidant defense could prevent oxidative stress and DNA damage. Selenoproteins like glutathion peroxidase 3 are part of the defense. **B,** Conditions of iodine deficiency increase levels of H2O2 and may increase the amount of oxidative stress and DNA damage. Selenium deficiency decreases selenoproteins and could thereby weaken antioxidative defense, which exacerbates oxidative stress and DNA damage. *ROS,* Reactive oxygen species; *DUOX system,* thyroid oxidase system; *TPO,* thyroid peroxidase; *H2O2*, hydrogen peroxidase; *T3*, triiodothyronine; *T4*, thyroxine..

Differential expression of additional antioxidant enzymes illustrates the importance of the antioxidant defense in the iodine-deficient thyroid gland.[14] Of note, glutathione peroxidases are selenium proteins. Selenium deficiency can further impair the antioxidant defense and thereby exacerbate oxidative stress (see Fig. 77.3).

In summary, the early molecular prerequisites for nodular/neoplastic transformation in the thyroid gland appear to consist of a sequence of molecular events that include oxidative stress and DNA damage as the trigger for somatic mutations. The oxidative burden is already detectable in the normal thyroid gland and is very likely to be linked to hormone synthesis and H2O2 production. Additionally, environmental conditions (e.g., iodine deficiency) have the potential to deteriorate this situation. In general, any external factor (e.g., smoking) that increases oxidative stress, causes DNA damage, or increases the somatic mutational rate aggravates the risk for tumorigenesis. Also, any factor that increases proliferation (e.g., goitrogens) can accelerate the development of a thyroid tumor.

Hot Thyroid Nodules

A TA is a monoclonal AFTN that synthesizes thyroxine (T4) and/or triiodothyronine (T3), resulting in eventual suppression of serum TSH and in subclinical or overt hyperthyroidism.[15] AFTNs harbor somatic gain-of-function mutations in the TSHR,[16] and the mutations may differ among TAs within the same multinodular goiter. Thyroid dysfunction is readily diagnosed with thyroid function tests, and, in the case of evidence for excessive hormone production, zones of autonomy can be detected through scintigraphy, if indicated. Somatic point mutations that constitutively activate the TSHR explain the clinical phenotype of hot thyroid nodules through their activation of the G_s or the G_s and $G_{q/11}$ pathways, resulting in a stimulation of proliferation, differentiation, and increased thyroid hormone synthesis. However, in different studies the prevalence of TSHR and Gs α mutations in hot thyroid nodules has been reported to vary from 8% to 82% and 8% to 75%, respectively. Available studies differ in the extent of mutation detection and the screening methods. A comprehensive study using the more sensitive denaturing gradient gel electrophoresis technique revealed a frequency of 57% TSHR mutations and 3% GNAS (the gene coding for the Gs α protein) mutations in 75 consecutive hot thyroid nodules.[17] These results raise the question of the molecular etiology of TSHR and GNAS mutation-negative nodules. In order to determine whether other gene(s) may be responsible for the remaining TSHR and GNAS mutation negative cases of hot thyroid nodules, whole-exome sequencing (WES) was performed for 13 TSHR and GNAS mutation-negative samples.[18] While no further causative mutation could be identified, WES revealed a recurrent hot spot mutation (c.1712A>G; p.Gln571Arg) in enhancer of zeste homolog 1 (*EZH1*). Targeted screening in an independent cohort confirmed a high frequency (27%) of this mutation in hot thyroid nodules. *EZH1* mutations were strongly associated with known (*TSHR, GNAS*) or presumed (*ADCY9*) alterations in genes involved in the cAMP pathway. Functional studies revealed that the *EZH1* mutation causes increased histone H3 methylation, as well as increased proliferation of thyroid cells. Hence, this study revealed a hot spot mutation in *EZH1* as the second most frequent genetic alteration in hot thyroid nodules.[18] The association between *EZH1* and *TSHR* mutations suggests at least a two-hit model for the pathogenesis of these tumors, whereby constitutive activation of the cAMP pathway and *EZH1* mutations cooperate to induce hyperproliferation of thyroid cells. Because WES did not reveal a further causative mutation for hot thyroid nodules, a very sensitive and comprehensive targeted next-generation sequencing panel has been developed that covers the whole coding sequence of the *TSHR,* as well as the *GNAS* hot spot loci c. 201 and c. 227.[19] This panel allowed further evaluation of the impact of *TSHR* and *GNAS* mutations on the molecular etiology of hot thyroid nodules in a large cohort of hot thyroid nodules.[20,21] Due to the higher sensitivity of the targeted next-generation sequencing panel compared with previously used methodologies, *TSHR* or *GNAS* mutations could be detected in 85% of hot thyroid nodules. Moreover, in an optimal sample set with multiple samples per nodule, the prevalence of *TSHR* and *GNAS* mutations rose to 96%. These results, in addition to the fact that no further causative driver mutations explaining the phenotype of hot thyroid nodules could be identified by previous WES, strongly support the hypothesis that *TSHR* and *GNAS* mutations are presumably the only somatic mutations leading to hot thyroid nodules.[19]

In addition to the intracellular signaling network that is connected to the TSHR, the extracellular action of different growth factors enhances the complexity of the signal flux into the thyroid cell. Growth factors like IGF-1, EGF, TGF-β1, and fibroblast growth factor stimulate growth and dedifferentiation of thyroid epithelial cells. Studies focused on insulin and IGF show a permissive effect of insulin and IGF-1 on TSH signaling and a cooperative interaction of TSH and insulin/IGF-1. Other studies suggest inactivation of TGF-β1 signaling in hot thyroid nodules due to constitutively activated TSHR (e.g., resulting from *TSHR* mutations).[22] This assumption is supported by the finding of a decreased expression of TGF-β1 messenger RNA (mRNA) after TSH stimulation of thyrocytes. Because TGF-β1 has been shown to inhibit iodine uptake, iodine organification, and thyroglobulin expression,[23] as well as cell proliferation in different cell culture systems, these findings suggest that inactivation of TGF-β1 signaling is a major prerequisite for increased proliferation in hot thyroid nodules.[24] Signal modulation of the TSHR that appears to define the etiology of hot thyroid nodules and the clinical phenotype could therefore take part at a number of stages and very likely involves genetic/epigenetic, sex-related, and environmental factors.

In vivo characteristics of TA include increased iodide uptake and thyroid peroxidase mRNA and protein content, as well as increased thyroid hormone secretion.[25] Upregulation of sodium-iodide symporter (NIS) and pendrin contributing to the augmented iodine-trapping characteristics of TA have been reported by other investigators.[25] Basal inositol phosphate generation was not found to be increased in toxic thyroid nodules, compatible with a predominant constitutive activation of the cAMP–protein kinase A cascade through TSHR or Gs_{α} protein mutations in TA and TMNG.[24] Stimulation of growth has been investigated in TA using the proliferation markers Ki67 and proliferating cell nuclear antigen.[25] However, the increase in the proliferation index in TA was found to be relatively low (2- to 3-fold) compared with the surrounding normal thyroid. These data are in agreement with the slow progression seen in TA and TMNG; however, they are difficult to reconcile with the evolution of a macroscopic TA from a single mutated cell (estimated number of 30 cell divisions to yield a nodule volume of ~1 mL),[24] and thus may more likely reflect the end stage rather than the initiation of disease.

Cold Thyroid Nodules

The term *cold* indicates reduced uptake of iodide or pertechnetate on scintigraphy. Because a histologic diagnosis is typically employed to exclude thyroid malignancy, many investigations of thyroid nodules only refer to the histologic diagnosis of thyroid adenoma. This histologic entity should not be confounded with the scintigraphically characterized entity *cold nodule,* which, like hot or warm (scintigraphically normofunctional) thyroid nodules can histologically appear as thyroid adenomas or adenomatous nodules according to the WHO classification. In contrast, focal hyperplasia is not very well explained at the molecular level and has been discussed in detail elsewhere as the cause of thyroid tumors.[26] A monoclonal origin has been detected for the majority of cold thyroid nodules, which implies nodular development from a single mutated thyroid cell (Fig. 77.1).[27]

With reference to their functional status (i.e., reduced iodine uptake), failure in the iodide transport system or failure of the organic binding of iodide had been detected as functional aberrations of cold thyroid nodules long before the molecular components of the iodine metabolism were known. Subsequently, a decreased expression or membrane localization of the NIS and, more likely, a defective cell membrane targeting of the NIS protein in thyroid carcinomas and benign cold thyroid nodules were suggested as the molecular mechanism underlying the failure of the iodide transport or uptake in cold thyroid nodules (reviewed in[28]).

A study of 40 cold thyroid adenomas and adenomatous nodules detected *RAS* mutations in only a single case.[27] Moreover, in the same set of cold thyroid nodules, no point mutations in the mutational hot spots of the *BRAF* gene were detected.[29] This is in line with the lack of *BRAF* mutations in benign follicular adenomas in other studies.[30]

Increased expression of histone mRNAs and of cell cycle–associated genes like *cyclin D1, cyclin H/cyclin dependent kinase (CDK) 7,* and *cyclin B* most likely reflect a molecular background that is permissive for increased cellular proliferation in cold thyroid nodules.[31] In line with the low prevalence of *RAS* mutations in cold thyroid nodules,[27] a reduced expression of RAS-MAPK cascade-associated genes was found, which may suggest a minor importance of this signaling cascade.

Euthyroid Nodules

Most of the literature on the molecular etiology of euthyroid nodules is focused on cold thyroid nodules. However, scintigraphically cold nodules are difficult to differentiate from scintigraphically isocaptant nodules.[32] It is therefore important to note that the vast literature on benign thyroid nodules comprises scintigraphically cold and scintigraphically isocaptant nodules, which make up approximately 50% to 85% and up to 40% of all nodules, respectively. *RAS* mutations are the most prevalent mutations reported in benign scintigraphically cold/isocaptant nodules (mostly designated as follicular adenoma), with a prevalence of 20% to 25%. In addition to benign thyroid nodules, *RAS* mutations have been described in approximately 30% to 45% of follicular thyroid carcinomas, 30% to 45% of follicular variant papillary thyroid carcinomas, 20% to 40% of poorly differentiated thyroid carcinomas, and 20% to 30% of anaplastic thyroid carcinomas.[33] The finding of *RAS* mutations in benign thyroid nodules, as well as in follicular patterned thyroid carcinomas such as follicular thyroid and follicular variant papillary thyroid carcinomas, suggests that *RAS*-positive benign nodules (follicular adenomas) could serve as a precursor for *RAS*-positive carcinomas.[33] However, additional genetic alterations such as *PTEN* deletions or *PIK3CA* mutations[34] are required to transform a benign thyroid nodule into a follicular thyroid carcinoma. Similarly to *RAS* mutations, the *PAX8/PPARG* fusion oncogene has been reported in both benign thyroid nodules and follicular thyroid carcinomas.[35] Thus, the same diagnostic problem, i.e., a large variation in the prevalence of for *PAX8/PPARG* gene fusions in benign tumors and malignant tumors, is present, akin to the scenario for *RAS* mutations. A comprehensive analysis of benign thyroid nodules based on whole-exome and transcriptome sequencing revealed mutually exclusive SPOP^{P94R}, EZH1^{Q571R}, and ZNF148 mutations in 24% of benign nodules.[36] However, a further study showed that the mutational profiles of benign thyroid nodules (follicular adenomas) and minimally invasive follicular carcinomas are very similar, and no mutational cluster could be identified separating the two tumor entities. Moreover, the comparison of gene expression profiles of benign thyroid nodules (follicular adenoma) and minimally invasive follicular carcinoma confirmed that these two neoplasias do not have significant transcriptional differences.[37] Finally, there is high interobserver variation for the respective histologic diagnoses where capsular and/or vascular invasion is the only criterion that allows one to differentiate follicular thyroid carcinoma from benign thyroid nodules.

KEY POINTS

- Iodine deficiency leads to increased oxidative stress. Somatic mutations induced by oxidative stress are a likely cause for benign clonal thyroid nodules.
- The etiology of multinodular goiter is based on a complex interaction between genetic susceptibility and environmental factors.

FAMILIAL AND SPORADIC NONAUTOIMMUNE HYPERTHYROIDISM

Autosomal dominant familial nonautoimmune hyperthyroidism was recognized as a separate entity in 1982 by Thomas et al.[38] At that time, the underlying etiology was unknown. After the cloning of the TSHR, it then became apparent that gain-of-function mutations can lead to several pathological entities: 1) somatic mutations can cause TAs[39] (see also earlier discussion); 2) germline mutations can be inherited in an autosomal dominant fashion and lead to familial nonautoimmune hyperthyroidism[40]; and 3) *de novo* germline mutations can cause sporadic nonautoimmune hyperthyroidism.[41] In contrast, biallelic loss-of-function mutations lead to compensated or overt hypothyroidism because of resistance to TSH.[42]

Patients with activating germline mutations in the TSHR typically have a goiter, but the characteristic signs associated with autoimmune hyperthyroidism, i.e., the presence of antibodies against the TSHR, endocrine ophthalmopathy, myxedema, and lymphocytic infiltration of the thyroid gland, are absent.[38] In the inherited form, the family history reveals familial clustering consistent with an autosomal disorder. In these families, the age of onset of hyperthyroidism is variable among affected individuals and depends, in part, on the activity of the mutated allele, as well as on other factors such as iodine intake and genetic background. In infants with neonatal hyperthyroidism, it is important to distinguish the more frequent and transient autoimmune form due to transplacental passage of stimulating TSHR autoantibodies from a mother with a history of Graves disease from sporadic nonautoimmune hyperthyroidism.[16] The latter patients tend to have germline gain-of-function mutations of the TSHR[43,44]; congenital hyperthyroidism due to a TA harboring a somatic *TSHR* mutation has been reported as an unusual variant.[16] Importantly, several of the children with severe neonatal hyperthyroidism presented with mild mental retardation. This could be due to a direct effect of excessive thyroid hormone levels on brain development or premature closure of the cranial sutures, which can involve exclusively the squamosal sutures.[41]

A definitive diagnosis of nonautoimmune hyperthyroidism can now be easily confirmed by direct sequencing of the coding region of the *TSHR* gene. The known mutations are accessible in the continuously updated TSHR database that includes more than 400 gain-of-function mutations and close to 200 loss-of-function mutations (tsh-receptor-mutation-database.org).[44] So far, 29 families and 20 children with sporadic occurrence of *TSHR* germline mutations have been reported, mainly in Europe.[44] Thyroid ablation is advocated as first-line treatment (surgery and/or radioiodine) for preventing relapses. Molecular analysis for germline *TSHR* mutations offers the possibility for family screening, preclinical diagnosis, and genetic counseling.[45] If the mutation is unknown, functional *in vitro* analyses are needed to demonstrate that the mutated allele confers constitutive activity to the receptor.

The therapy of patients with nonautoimmune hyperthyroidism can be challenging. The entity is not always readily recognized, and can be confused with Graves disease. This may result in inadequate therapeutic control and frequent relapses in patients treated with thionamides or insufficient amounts of radioiodine. For a definitive cure, it is paramount to destroy all thyroid tissue, either by thyroidectomy followed by radioiodine therapy, or by radioiodine therapy alone. Particularly in infants and small children, the use of thyreostatic therapy is a valid option before considering a definitive therapeutic modality later in life.

IODINE-INDUCED HYPERTHYROIDISM

In individuals with underlying thyroid disease, excessive dietary iodine intake or the administration of iodine-containing compounds can result in iodine-induced thyrotoxicosis (IIT) or hypothyroidism.[15,46] IIT is also referred to as the *Jod-Basedow* phenomenon (Jod meaning iodine in German; Karl von Basedow, the German physician who described the signs of thyrotoxicosis associated with exophthalmos and goiter, i.e. Graves disease). Of note, Graves disease is typically referred to as Basedow disease on the European continent. The condition was reported as early as 1821 by Coindet, who realized that the administration of potassium iodide can lead to reduction in goiter volume but may induce toxic effects with a clinical presentation that reflects IIT.

For adults, the recommended daily allowance for iodine is 150 mcg per day. The tolerable upper intake level for adults has been set to 1100 mcg/day.[47] Normally, the thyroid is protected against iodine excess by the *Wolff–Chaikoff* effect, which results in an immediate reduction in iodide uptake, organification, and thyroid hormone biosynthesis and secretion.[48] Impressively, most individuals with a normal thyroid gland tolerate even a chronic excess of 30 mg up to 2 g iodide per day without clinical symptoms. However, the autoregulatory mechanisms mediated by the Wolff–Chaikoff effect are no longer functional or are impaired in diseased thyroid tissue, in which exposure to even modest amounts of excessive iodine can induce IIT in susceptible individuals. IIT is particularly prevalent in patients with multinodular goiter that contain nodules with an autonomy of function, but can also occur in individuals with autoimmune thyroid disease. In regions with a history of iodine deficiency, where multinodular goiters are particularly prevalent, the implementation of iodination programs has therefore often been associated with an increase in IIT.[15]

The possible sources of excess iodine or iodide are innumerable and include nutrients, radiological contrast agents, disinfectants, expectorants, and drugs.[15]

A particularly common problem in clinical practice consists in amiodarone-induced thyrotoxicosis (AIT) (see Chapter 84).[49] By weight, amiodarone consists of 37% iodine; hence, a 200 mg tablet contains approximately 75 mg iodine. AIT is subdivided into two distinct entities: AIT1 is caused by iodine-induced hyperthyroidism in patients with nodular goiters or underlying Graves disease, and AIT2 is caused by a destructive thyroiditis resulting in the release of thyroid hormones. Mixed forms of AIT1 and AIT2 do exist, and it can be difficult to distinguish the two forms. With improved nutritional iodine intake, the prevalence of AIT2 seems to increase relative to AIT1. AIT1 is treated with thionamides (sometimes in combination with perchlorate in countries where the drug is available), and AIT2 is treated with glucocorticoids. If the etiologic mechanism cannot be clearly defined, which is frequently the case in clinical practice, thionamides are frequently combined with glucocorticoid therapy. In patients with AIT that is difficult to control, thyroidectomy may be indicated.

Radiographic iodinated contrast media (ICM) are a common source of high amounts of iodine, with a typical iodine content of 320 to 370 mg/mL.[47] In a retrospective case-control study evaluating the association between ICM use and thyroid dysfunction, the risk for developing either hyperthyroidism or hypothyroidism after exposure has been estimated to be increased by 2- to 3-fold.[50] In contrast, in a systematic review/metaanalysis, the overall estimated prevalence of overt hyperthyroidism after ICM exposure was extremely low (0.1%, 95% confidence interval: 0–0.6), suggesting that the concern for IIT is often overestimated.[51] Symptomatic patients can be treated transiently with a beta-blocker and, if needed, thionamides. In patients at high risk for thyrotoxicosis, prophylactic administration of thionamides can be considered before the administration of ICM for the imaging study.[47]

In TA and TMNG, a sudden increase in function can be induced by the administration of excessive amounts of iodine, e.g., in the form of contrast media used for angiography and computed tomography (CT) scans or by iodine-containing drugs, e.g., amiodarone. In the European Study Group of Thyrotoxicosis, iodine contamination was found in 36.8% of patients from iodine-deficient areas with thyrotoxicosis.[52] Severity of iodine deficiency, autonomous thyroid cell mass, and older age have been proposed as risk factors for the development of iodine-induced thyrotoxicosis (see Chapter 84).

EPIDEMIOLOGY, OCCURRENCE, AND NATURAL HISTORY OF EUTHYROID AND HOT THYROID NODULES

The natural history of multinodular goiter, with respect to goiter growth and function, varies and is difficult to predict in a given patient. The spontaneous growth rate in selected populations has been estimated to be up to 20% yearly[53] but is usually much lower. No specific parameter exists that can predict the growth potential of multinodular goiter, which can be accurately assessed by serial yearly measurements of the size of the goiter and individual nodules by ultrasonography.

Painful nodules are usually the result of hemorrhage into a nodule or a cyst in the goiter. The diagnosis is readily made by ultrasonographic examination and fine-needle aspiration cytology (FNAC). Multinodular goiter is not usually associated with a significantly increased risk for the development of thyroid malignancy. The risk for malignancy in thyroid nodules occurring within a multinodular goiter has not been completely clarified, but most authors find a similar frequency in uni- and multinodular goiters, of approximately 5%.

Thyroid autonomy is widely viewed as a manifestation of benign disease, and current guidelines recommend that hot nodules in patients with suppressed thyrotropin levels be excluded from further malignancy risk stratification. However, 61 case reports indicating the presence of thyroid carcinoma within a hot nodule were published from 1972 to 2018. Detailed pathologic analyses of reported “toxic thyroid cancer” cases (0.7%–6% in different series) have shown that, if classified correctly, the cancer (a) usually occurred coincidentally within the same or even in the contralateral thyroid lobe, (b) mostly represented a papillary thyroid microcarcinoma (<1 cm), and (c) was rarely located within the hot nodule itself. A recent study demonstrated equivalent malignancy rates in hyperthyroid hot nodules and euthyroid hot nodules, with an overall malignancy rate of 8.5%.[54] Furthermore, a recent animal study observed the development of large papillary thyroid cancer in nearly all mice with a constitutively active TSHR mutation knock-in, the most common etiology of hot nodules and other nonautoimmune hyperthyroidism.[55] Eighteen cases of hyperfunctioning thyroid carcinomas with somatic constitutively activating TSH mutations have been reported, highlighting the need for elucidating the underlying mechanism.[44]

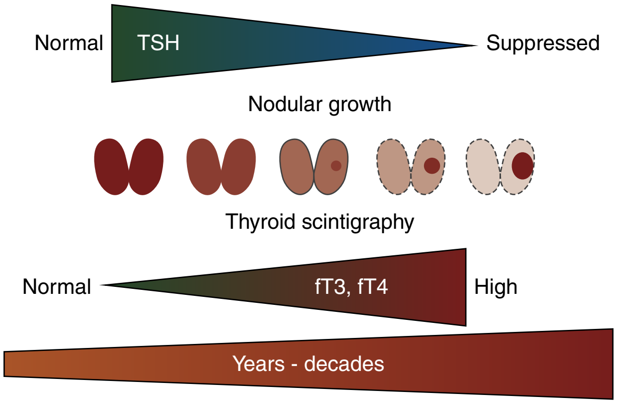

Fig. 77.4 Evolution of a toxic nodule from a scintigraphically undetectable clone of thyroid cells with a somatic thyroid-stimulating hormone (TSH) receptor mutation in a euthyroid thyroid gland to a hot nodule with increasing suppression of TSH.

Patients with nontoxic multinodular goiter can become hyperthyroid or, less commonly, hypothyroid. Hyperthyroidism in such patients often develops insidiously, in contrast to that associated withs Graves disease. It often begins with a prolonged period of subclinical hyperthyroidism characterized by low serum TSH and normal serum free T4 and T3 concentrations. This hyperthyroid state is the consequence of goiter growth and an associated increase in the mass of autonomously hormone-producing thyroid cells. Long-term studies on patients with TA have shown that the natural course tends to be slow, requiring years or decades (see Figs. 77.2 and 77.4). Sandrock et al. reported an overall 4.1% annual incidence of thyrotoxicosis in a group of 375 untreated euthyroid TA patients in Germany who were followed for a mean of 53 months.[56] Hamburger highlighted the correlation between nodule size and development of thyrotoxicosis in a group of 349 patients with TA: 93.5% of patients with overt thyrotoxicosis had TA greater than 3 cm in size, and patients with a euthyroid TA of greater than 3 cm in size had a 20% risk of developing thyrotoxicosis during a 6-year follow-up period, as opposed to a 2% to 5% risk in patients with nodules less than 2.5 cm in size (see Figs. 77.2 and 77.4).[57]

Data on progression from euthyroid to subclinical and overt thyrotoxicosis in patients with multinodular goiter are scarce. An incidence of 9% to 10% of overt thyrotoxicosis was proposed in two studies during a follow-up period of 7 to 12 years.[13,57,58]

In a large population-based cross-sectional study in an iodine-deficient area, nodular autonomy increased with age and reached 15% in older adults. It appears from a few longitudinal studies that, within 5 years, hyperthyroidism will emerge in approximately 10% of patients with a nodular goiter.

Iodine deficiency is still the most frequent single cause of multinodular endemic goiter worldwide (see Chapter 76). Considerable regional variation exists even in nonendemic goiter areas. Illustrating the influence of iodine intake on the epidemiology of sporadic goiter, 31 of 423 (7.3%) 68-year-olds had goiter in Jutland, Denmark (low iodine intake area), versus 2 of 100 (2%) in Reykjavik, Iceland (high iodine intake area).[59] In the Danish population, the goiter prevalence decreased 4 years after iodization of salt, while the prevalence of thyroid nodules remained unchanged. As with nontoxic goiter, iodine intake is of paramount importance for the occurrence of hyperthyroidism. In Denmark, a country with a borderline sufficient iodine intake, multinodular toxic goiter accounts for 44% of patients with hyperthyroidism,[59] whereas in Iceland, with a high iodine intake, there is a lower proportion of multinodular goiter (6%) and more cases of Graves disease.[59]

Thyroid nodules and cystic lesions are extremely common in the general population; their prevalence increases with age, female sex, and adiposity.[60-62] When the thyroid is evaluated through neck palpation, the prevalence is approximately 5% in iodine-sufficient regions. However, the widespread use of neck sonography and other imaging techniques such as CT, magnetic resonance imaging, and positron emission tomography-CT (PET-CT) has shown that their prevalence is as high as 65%.[63,64] Many of these *thyroid incidentalomas* are small and benign and have no further clinical relevance. Hence, the challenge consists in identifying the nodules that are associated with thyroid dysfunction, clinically significant thyroid carcinomas, or nodules that result in the compression of adjacent structures, while avoiding unnecessary testing and surveillance that result in significant economic and personal burden.

The vast majority (90%–95%) of thyroid nodules are benign, although this frequency is influenced by the clinical presentation, personal medical and family history, and the mode of detection. Risk factors for malignancy include radiation exposure,[60] a family history of thyroid cancer, and certain hereditary syndromes such as Cowden syndrome, Gardner syndrome, familial adenomatous polyposis, and, for medullary thyroid cancer, multiple endocrine neoplasia type 2.[60] In nodules detected by PET-CT, increased standardized uptake values correlate with a higher risk of malignancy[65].

The characterization of nodules associated with a normal thyroid function leans heavily on the use of ultrasound, which enables prediction of malignancy risk.[64,66-68] Although nodule growth is often considered as a risk factor for malignancy, it is a parameter with poor predictive value.[68]

Screening for thyroid cancer is not recommended in asymptomatic individuals.[69] Active screening, together with the advent of novel imaging modalities, has contributed to the excessive detection of large number of clinically irrelevant small papillary thyroid carcinomas[70] and to the phenomenon of *overdiagnosis,* resulting in an epidemic of thyroid cancer.[71]

THYROID NODULE DIAGNOSTIC PATHWAY TO DISTINGUISH BENIGN AND MALIGNANT THYROID NODULES

Higher levels of healthcare access, both sociodemographic and age-based, are associated with higher papillary thyroid cancer incidence rates. However, despite the 3-fold increase in incidence over three decades, the mortality rate has remained unchanged. Thus, together with the large subclinical reservoir of occult papillary thyroid cancers, there is evidence for the widespread overdiagnosis of papillary thyroid cancers.[72] The further workup of thyroid nodules after clinical and laboratory investigations will not only be determined by the outcome of the clinical and laboratory investigations, but also, most importantly, by local healthcare settings. The applicability and relevance of published evidence and best practice summarized in the respective guidelines[66,73,74] and in the chapters on imaging and ultrasound (see Chapter 69) and on FNAC (see Chapter 70), vary and depend, in part, on the framework of the healthcare system for thyroid nodule and thyroid cancer diagnostics. It is best to organize and optimize thyroid nodule and thyroid cancer diagnostics as a pathway. The performance and outcomes of each step in this pathway will have impact on all further steps. Deficiencies for one of the diagnostic steps or expertise cannot be compensated by (over)emphasizing any other step or expertise. For example, insufficient ultrasound malignancy risk stratification or inconsistent terminology for the description of ultrasound findings will result in higher FNAC rates with subsequent increases in false positives for FNAC and low malignancy yield for diagnostic lobectomies. Insufficient cytology expertise or nonadherence to cytology classifications cannot be compensated for by molecular diagnostics. Lack of preoperative FNAC application will lead to low yield of malignancies after diagnostic lobectomies, with unnecessary surgical complications and postoperative thyroid hormone replacement.[75] The initial requirement for a thyroid nodule and thyroid cancer diagnostic pathway is the characterization of a nodule using an ultrasound-based risk stratification scheme.[76] If indicated, this is followed by a biopsy and a cytological evaluation adhering to an internationally accepted convention (i.e., the Bethesda system).[77] Based on the cytology results and the clinical presentation, the indication for or against surgery can then be established. The representation of the respective medical expertise by different medical disciplines and the availability of respective quality insurance data will depend on the level of heathcare (primary, secondary, or tertiary) and the respective healthcare system with its respective incentives and restrictions, and most importantly its respective different degrees of integration or fragmentation. Also, different medical training and specialization systems will determine if the ultrasound expertise is mostly restricted to radiology or if fellowship training for cytopathology with resulting broad cytology expertise is available or not, and so on.

Because most thyroid nodules are incidental findings on imaging studies, implementation of a structured pathway is key for thyroid nodule workup.

The available clinical endocrine, ultrasound, cytology, and surgical expertise, their extent of integration in a diagnostic pathway, the implementation and healthcare quality insurance of the diagnostic pathway (Fig. 77.5A), and its integration with the primary care setting (Fig. 77.5B) will determine the diagnostic outcomes and the quality of care for patients with thyroid nodules or thyroid cancer. It is therefore self-evident that local process quality and local diagnostic outcomes and the local quality of care for patients with thyroid nodules can only be determined by local healthcare quality insurance data. Most of the evaluations of thyroid nodule ultrasound malignancy risk stratification systems or determinations of malignancy rates for the different Bethesda thyroid nodule FNAC categories were performed in select secondary or tertiary care settings with high-level FNAC operator and cytology expertise, and may not necessarily be applicable to a nonspecialized environment.[78]

Clinical Examination

The majority of patients with one or several thyroid nodules are asymptomatic. The medical history may reveal compressive symptoms such as dysphagia, dysphonia, hoarseness, respiratory complaints, or stridor. Pertinent clinical signs and symptoms are listed in Table 77.1, and diagnostic aspects are summarized in Table 77.2. Occasionally, hemorrhage into a nodule or cyst can lead to acute compressive symptoms. Pain can occur in patients with inflammatory or infectious processes in the thyroid. The Pemberton sign, defined by facial congestion and respiratory difficulties after elevating both arms, is suggestive for compression of the thoracic inlet. It can be associated with multinodular goiters with extension into the upper mediastinum, as well as with other masses causing a superior vena cava syndrome.[79]

The clinical examination includes inspection of the neck for the presence of a goiter and palpation of the thyroid and the neck for the detection of nodules and cervical lymph nodes. Although palpation is useful for the identification of larger nodules and tenderness (e.g., in the context of a [sub]acute thyroiditis), it has a low sensitivity and specificity. Many nodules are relatively small and cannot be detected if located in the posterior parts of the gland. Similarly, many pathological lymph nodes escape detection by palpation. The widespread availability of ultrasound, which provides detailed structural information of the thyroid and allows stratifying the malignancy risk of thyroid nodules and lateral neck lymph nodes,[64,66,67] has fundamentally transformed clinical practice. Clinical features in a patient with thyroid autonomy can be attributed to (a) symptoms of thyrotoxicosis and (b) the nodular goiter.

The clinical presentation of thyrotoxicosis varies with age, and in the elderly it is often not symptomatic ("apathetic hyperthyroidism").[13] In a series of 84 French patients with overt thyrotoxicosis, atrial fibrillation and anorexia dominated in the older age group (≥70 years), while classical signs of thyrotoxicosis, e.g., nervousness, weight loss despite increased appetite, palpitations, tremor, and heat intolerance were more frequently observed in younger patients (≤50 years).[80] Alternatively, a patient may present with a lump or disfigurement of the neck, intolerance of a tight collar, or increase in collar size. Dysphagia or breathing difficulties due to esophageal or tracheal compression may be apparent, especially with large TMNG.[80]

Subclinical thyrotoxicosis, defined by low or suppressed serum TSH with normal free T4 and free T3 levels is more commonly observed in older patients with TMNG.[2,80] Moreover, the incidental finding of low or suppressed TSH levels on routine investigation for other indications is frequently the first evidence for the presence of thyroid autonomy, particularly in regions with iodine deficiency. Subclinical thyrotoxicosis may be associated with atrial fibrillation and a reduced bone density.

Laboratory Investigations

Thyroid function should be determined in all patients with structural abnormalities of the thyroid, including thyroid nodules.[66] The initial step consists in the measurement of a serum TSH concentration. In patients with suppressed TSH levels, the peripheral hormones (T4 and T3) should also be determined. If subclinical or overt hyperthyroidism is confirmed, thyroid scintigraphy can be performed in order to detect AFTNs. In patients with elevated TSH levels, the measurement of T4 levels and thyroid autoantibodies permit diagnosis of autoimmune thyroid disease. Of note, Hashimoto thyroiditis typically has a very characteristic pattern on ultrasonography.

The measurement of thyroglobulin is not recommended in the evaluation of patients with nodular thyroid disease because it does not allow discrimination between benign and malignant conditions.[66] In patients with an established diagnosis of thyroid cancer originating from thyroid follicular cells, very high preoperative thyroglobulin levels may suggest locoregional or distant metastases, but thyroglobulin is not measured routinely by all experts in this setting.[66]

Calcitonin is a marker for medullary thyroid cancer. Although some experts suggest that measuring calcitonin is useful in the workup of thyroid nodules, this approach remains controversial.[81] Major guidelines do not support measuring calcitonin unless there is a family history for medullary thyroid cancer or suspicious cytologic characteristics because of the low yield and an unfavorable cost-benefit ratio.[66]

Diagnosis of Thyroid Autonomy

Diagnosis of thyroid autonomy is based on three characteristics:

1. Confirmation of clinically suspected thyrotoxicosis by an abnormal thyroid function test. Typically, there is overt thyrotoxicosis (low TSH, high free thyroid hormones). However, dependent on the autonomous cell mass, subclinical thyrotoxicosis (TSH low, free T3 and free T4 normal) or even euthyroidism may be present.
2. Presence of palpable or sonographic nodule(s).
3. Increased radionuclide uptake in the nodule(s) concomitant with a decreased uptake in the surrounding extranodular thyroid tissue. The most commonly used isotopes are ^{99}mTc, ^{123}I, and ^{131}I, which are transported into the thyrocytes by the NIS, but only iodine is organified. Several studies have revealed a comparable diagnostic value of the these isotopes. However, discrepancies due to trapping only nodules can be found in approximately 5% of hot nodules, mostly with normal serum TSH. The advantage of ^{99}mTc, which is more frequently used in Europe, is its low cost.[82]

If thyroid autonomy is suspected in an euthyroid patient, a "suppression" scan can be performed after administration of

thyroid hormone (i.e., 75 µg/day T4 for 2 weeks followed by 150 µg/day for 2 weeks), after which uptake in all nonautonomous tissue will be suppressed, and thyroid autonomy is unmasked. Measurement of thyroid autoantibodies is not routinely performed in TA and TMNG. However, in iodine-deficient areas, distinction between Graves disease and TMNG can be difficult if extrathyroidal manifestations of the former are absent and diagnostic findings are "atypical," e.g., presence of thyroid nodules (~27%–34% by ultrasonography) in suspected Graves disease patients and patchy rather than diffuse uptake on scintigraphy. In these conditions, determination of TSHR antibodies is helpful to establish the correct diagnosis.[83] Urinary iodine excretion can be measured in case

TABLE 77.1 Clinical Signs and Symptoms of Multinodular Goiter

- Slowly growing nodular anterior neck mass
- Tracheal deviation or compression, upper airway obstruction, dyspnea, dysphonia
- Occasional cough and dysphagia, globus sensation
- Sudden pain or enlargement secondary to hemorrhage
- Superior vena cava obstruction syndrome
- Pemberton's sign: obstruction of the thoracic inlet by extending the arms over the head
- Gradually developing hyperthyroidism
- Iodide-induced thyrotoxicosis
- Recurrent nerve palsy (rare)
- Phrenic nerve palsy (rare)
- Horner syndrome (rare)
- Enlargement during pregnancy

TABLE 77.2 Diagnosis of Multinodular Goiter

- Multinodularity on examination
- Asymmetry, tracheal deviation
- Thyroid-stimulating hormone normal or decreased, free thyroxine and free triiodothyronine normal or increased, thyroglobulin elevated
- Calcitonin normal
- Thyroid antibodies negative in approximately 90%
- Scintigraphy with hot and cold areas
- Ultrasound finding of nodularity (nonhomogeneity); cysts and calcifications are common
- Computed tomography, magnetic resonance, positron emission tomography/computed tomography imaging demonstrating a nonhomogeneous mass
- Lung function testing may demonstrate impaired inspiratory capacity
- Benign cytology by fine-needle aspiration of dominant nodules

of suspected iodine contamination. CT and magnetic resonance imaging techniques are not routinely indicated for the diagnosis of thyroid autonomy, but may be used for presurgical planning in patients with large and partly intrathoracic goiters.

Scintigraphy. The American Thyroid Association (ATA) guidelines recommend that a radionuclide thyroid scan should be performed if the serum TSH is subnormal.[66] However, the American Association of Clinical Endocrinologists/American College of Endocrinology/Associazione Medici Endocrinologi (AACE/ACE/AME) thyroid nodule guidelines recommend performing thyroid scintigraphy only in the presence of a thyroid nodule or MNG in combination with a suppressed TSH level, or when ectopic thyroid tissue or a retrosternal goiter is suspected. In iodine-deficient regions, thyroid scintigraphy is recommended to exclude autonomy of a thyroid nodule or MNG even when the TSH level is low-normal.[73] The latter is supported by a meta-analysis of eight studies with 2761 hot thyroid nodules that reported a pooled prevalence of hot nodules with normal TSH levels of 50%.[84] Moreover, thyroid nodules are not only classified as either "cold," or "hot," but may also show "normal" uptake on scintigraphy. In Europe, approximately 50% to 85% of all nodules are "cold," up to 40% are scintigraphically indifferent, and approximately 10% are "hot."[85,86] Moreover, there is some geographic variation that is influenced by iodine intake, as well as the clinical setting. Smaller thyroid nodules (<1 cm) may not be detectable by planar scintigraphy, and hot thyroid nodules in the posterior part of the thyroid may be obscured by overlying normal tissue, thus requiring single-photon emission CT analysis for their detection. The goal of scintigraphy is not only to identify a hot nodule, but also to exclude hot nodules from further malignancy risk stratification based on their very low risk for malignancy.

Malignancy Risk Stratification using Thyroid Ultrasound

Malignancy risk stratification of thyroid nodules with ultrasound requires a structured evaluation and consistent description of all pertinent characteristics using a common dictionary of adjectives followed by a stratified interpretation.[87] This is essential for a meaningful use of any of the currently available Thyroid Imaging Reporting and Data Systems (TI-RADS).[64,66,67] The European Thyroid Association and the American College of Radiology have developed specific lexicons for their risk-assessment systems. Definitions of nodule characteristics like extrathyroidal extension, echogenicity, shape, or microcalcifications can significantly impact the diagnostic performance of the respective classification system. The interobserver agreement for ultrasound-based risk-stratification systems is only fair to moderate (kappa, 0.34–0.44). Specific training is required to increase the operators' ability to recognize and describe these features.[88] An overview of the pertinent nodule characteristics evaluated by such systems, FNAC indications, and follow-up recommendations of four international practice guidelines is summarized in Chapter 69. The nodule characteristics considered in the risk scores are very similar for these systems—structural composition, echogenicity, shape, margins, and echogenic foci—and risk classes are defined by two or more nodule features. The exception to this is the American College of Radiology (ACR) TI-RADS classification, which assesses the same characteristics individually.[67] Each is rated with a numerical score, and the sum of the five scores determines the risk class to which the nodule is assigned. There is some degree of heterogeneity across systems regarding the definitions of certain nodule features, the relative weight assigned to individual features, and the size criteria used for FNAC recommendations. For each risk class, size cutoffs are used to identify lesions whose FNAC can safely be deferred. Prospective evaluations of the recommendations by the British Thyroid Association, the ATA, and the AACE/ACE/AME concluded that the respective classification systems had similar predictive values of malignancy in high-risk classes. The ATA and AACE/ACE/AME systems were effective for ruling out the need for FNAC in ultrasound low-risk nodules. Substantial interobserver agreement was noted for the respective classifications.[76] A further prospective evaluation of the ATA, AACE/ACE/AME, and ACR TI-RADS systems concluded that the ACR TI-RADS classification system has the highest area under the receiver operating characteristic curve for the identification of cytological high-risk nodules. The ATA classification left "unclassified" some nodules with a relatively high risk of malignancy.[89] There is also substantial variability of the ability to decrease the number of unnecessary FNACs in the different stratification systems. In a prospective study, the ACR TI-RADS outperformed four other stratification systems for the reduction of the number of biopsies performed on nodules later diagnosed as benign.[90] The ACR system classified more than one half of the FNACs as deferrable, with a false-negative rate of only 2.2%. All these evaluations were performed at referral centers; thus, the validity of these results in the primary care setting needs further validation. Moreover, it is important to consider that the thyroid nodule malignancy risk stratification systems were developed mainly for the detection of papillary thyroid cancers. Their ability to detect follicular thyroid or medullary thyroid carcinomas requires further study. Current efforts focus on establishing an integrated international thyroid nodule ultrasound malignancy risk classification system based on a validated lexicon and incorporating state-of-the-art techniques,[91] as well as electronic algorithmic tools[92] and machine learning approaches (artificial intelligence) with the goal of reducing the number of unnecessary FNAC evaluations. Of note, depending on the respective referral setting and the operator training, approximately half of the thyroid nodules evaluated with one of the thyroid nodule ultrasound malignancy risk stratification systems can be characterized as very likely benign, with a very low 0.3% false-negative rate.[64] The remaining thyroid nodules with suspicious ultrasound malignancy characteristics should be subjected to FNAC based on stratified guideline-based recommendations.

Fine Needle Aspiration Cytology

FNAC is performed under ultrasound guidance by the following two commonly used techniques. In the parallel technique, the needle enters adjacent to the probe footprint along its long axis and is visualized from the skin entry point as it advances into the thyroid nodule. For the perpendicular technique, the needle is inserted perpendicular to the probe footprint with an angle determined by the thyroid nodule depth. Only the tip of the needle is visualized when it enters the nodule. The FNAC sample can be obtained either by applying gentle suction or without suction, the so-called capillary technique. The further preparation of the cytology material may either use the classic smearing on glass slides or liquid preparations, for which the choice is made together with the respective cytopathologist. Complications of FNAC are exceedingly rare. FNAC as the next step in the thyroid nodule diagnostic pathway should be reserved for thyroid nodules with a FNAC indication according to a stratified thyroid nodule ultrasound malignancy risk assessment (see Chapter 69) or clinical risk factors. Like the thyroid nodule ultrasound results, the FNAC results play a key role in the differential diagnostic pathway for the further workup and therapy of thyroid nodules.

The updated version of the Bethesda System for Reporting Thyroid Cytopathology (BSRTC) provides a robust diagnostic framework and guidance for the evaluation of the cytologic material.[77] Its recommended diagnostic categories are summarized in Chapter 70. Whereas the BSRTC provides evidence-based guidance for the malignancy risks in the respective cytology classes summarized in Chapter 70, the published variability for the percentages of assignment of the six cytology categories and their respective malignancy risks vary greatly. A metaanalysis reported cytologically benign results for 39% to 74% of the nodules tested and found that 2% to 16% of thyroid FNAC samples are cytologically malignant. An atypia of undetermined significance/follicular lesion of undetermined significance (AUS/FLUS) result was observed in 1% to 27%, a follicular neoplasm/suspicious for follicular neoplasm (FN/SFN) result in 1% to 25%, a suspicious-for-malignancy (SFM) result in 1% to 6%, and a nondiagnostic result in 2% to 24% of samples.[93] Due to the high interobserver variations in AUS/FLUS and FN/SFN diagnoses, consensus cytopathology is an effective way to reduce discrepant or indeterminate FNAC results. Recently, because of its indolent nature, it was proposed that the entity "noninvasive encapsulated follicular variant of papillary thyroid cancer" be reclassified as "noninvasive follicular thyroid neoplasm with papillary-like nuclear features" (NIFTP).[94] Of note, the diagnosis of NIFTP is established on histological grounds. The risk of malignancy in most BSRTC categories, most significantly the AUS/FLUS, FN/SFN, and SFM categories (see Chapter 70), will thus depend on the local prevalence of NIFTP. Most importantly, determination of local malignancy risks for the different BSRTC classes and the respective percentages for their local use is required by local evaluation and local quality insurance investigation, which will also depend on the local practice setting and resulting local prevalence data.[78] According to the BSRTC, most thyroid nodules subjected to FNAC are benign based on cytology and have an overall low malignancy risk that is less than 5%. Follow-up for an average of 8.5 years for initially benign thyroid nodule FNACs results in a false-negative rate of 1% and confers negligible mortality risk for these false positives during long-term follow-up. Because these malignancies were adequately treated despite detection at a mean 4.5 years after a falsely benign cytology, these data support a recommendation for repeat thyroid nodule evaluation 2 to 4 years after the initial benign FNAC, depending on ultrasound malignancy risk assessment. However, local outcome and quality insurance data are key for the application of this recommendation. Most papillary thyroid cancers and half of medullary thyroid cancers (MTC) can be detected by FNAC. Unfortunately, FNAC was only used in one fifth of patients undergoing surgery for a single thyroid nodule in Germany,[95] and similarly low frequencies of preoperative FNAC were reported in Belgium and France.[75] The deficiency that only half of MTCs are detected by FNAC[96,97] including the use of calcitonin immunocytology can be compensated for by preoperative calcitonin determination in suspicious cases without a family history for multiple endocrine neoplasia type 2 and using assay-, sex-, age-, and BMI-specific reference values for calcitonin assays.[98] The preoperative MTC diagnosis is important for enabling the correct first-line surgery with central compartment lymph node dissection in respective cases according to current guidelines.[99] Moreover, thyroid nodule FNAC has the inherent limitation of not being able to distinguish between benign thyroid adenomas or adenomatous nodules and follicular thyroid carcinomas (FTCs), because this differential diagnosis relies on the histologic criteria of capsular and/or vascular invasion. Therefore, around 20% of FNACs are indeterminate and classified as AUS/FLUS or FN/SFN with malignancy risks of 10% to 30% and 25% to 40% according to BSRTC (Chapter 70). For AUS/FLUS or FN/SFN, a repeat FNAC can be useful to clarify the cytologic diagnosis. However, a second FNAC provides a definitive diagnosis for only 40% of nondiagnostic and AUS/FLUS cytologies.[100] Moreover, if the risk stratification of nodules is well performed by ultrasound, the utility of this approach may be further reduced. Traditionally, diagnostic lobectomy has been required to allow a definitive histologic diagnosis for indeterminate thyroid nodules. This is obviously associated with risks and cost, and if the histology demonstrates the presence of a malignant nodule after lobectomy, this may require subsequent completion thyroidectomy. Histologic outcomes of patients stratified by FNAC for a diagnostic lobectomy suggest that up to 60% of patients were over- or undertreated with an initial surgery. Forty-two percent had potentially been overtreated with a hemithyroidectomy for benign disease when no other indication was recorded. Conversely, 17% had potentially been undertreated by the initial surgery, with the need for completion thyroidectomy.[101] Therefore, molecular diagnostics of indeterminate (AUS/FLUS and FN/SFN) FNAC has been recommended,[66,73] but these tests are currently not available or covered in many healthcare systems.

Molecular Diagnostics of Indeterminate Thyroid Nodule Cytologies

No molecular diagnostic test can replace or resolve deficiencies of a multidisciplinary approach to the management of patients with thyroid nodules. As part of an integrated approach of careful clinical, ultrasound, and FNAC assessment with local outcome data, molecular testing may be able to improve diagnostic outcomes for thyroid nodules by identifying patients with an indeterminate FNAC as most likely benign with less than 5% false negatives, thus obviating diagnostic

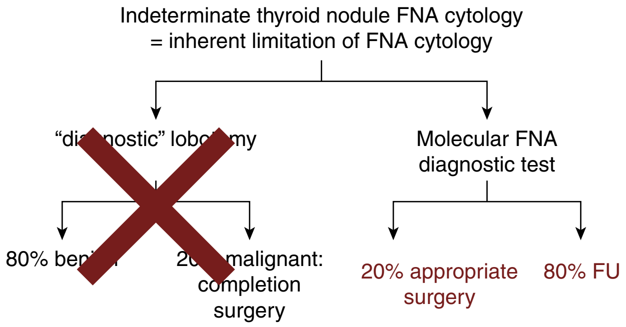

Fig. 77.6 **Diagnostic impact of molecular diagnostics of indeterminate thyroid nodule cytology as part of a diagnostic pathway.** A molecular fine-needle aspiration cytology test with high positive predictive value and >95% negative predictive value based on local data may replace diagnostic lobectomy for Bethesda System for Reporting Thyroid Cytopathology atypia of undetermined significance/follicular lesion of undetermined significance or follicular neoplasm/suspicious for follicular neoplasm cytology by appropriate surgery (lobectomy for mutations with low malignancy risk mutations or total thyroidectomy for mutations with high malignancy risk mutations) or follow-up.

lobectomy, or by identifying patients with malignant lesions or a high likelihood for malignancy for total thyroidectomy as definitive surgical treatment (Fig. 77.6).

Currently available molecular FNAC tests are based on testing for somatic mutations, gene expression evaluation, and microRNA (miRNA)-based classifiers.[102-107] The ThyroSeq test (version 3) uses targeted next-generation sequencing analysis of 112 cancer-related genes to identify point mutations, gene fusions, copy number alterations, or abnormal gene expression. Validation in 257 cytologically indeterminate nodules with surgical pathology reported a sensitivity of 94% and a specificity of 82%, with a negative predictive value of 97% and a positive predictive value of 66%. The test may eliminate the need for diagnostic surgery in up to 61% of patients with indeterminate nodules.[103] The Afirma Genomic Sequencing Classifier uses RNA sequencing and consists of 12 classifiers composed of 10,196 genes. It has a reported specificity of 68% and a positive predictive value of 47% with a sensitivity of 91% and a negative predictive value of 96%.[103] It is expected to reduce the frequency of diagnostic surgeries.[108] Thus, the ThyroSeq and Afirma assays reported positive and negative predictive values that make them suitable for use in both rule-in and rule-out testing. The validation studies for both tests reported sufficient sensitivities and specificities to be used as rule-in or rule-out tests for indeterminate FNACs. However, the validation study cohort for the Afirma assay was not representative of the populations in whom the assay has been used, thus calling into question its reported diagnostic performance, including its negative predictive value.[109] In the case of availability of similar postmarketing studies for the ThyroSeq test, a similar problem would likely also surface for the ThyroSeq test, because the validation study was mostly performed in tertiary referral centers. These findings emphasize once again the requirement for local evaluation of test performance as part of a diagnostic pathway. Currently, the further remaining problems are a lack of independent validation studies, a lack of long-term outcome studies for ThyroSeq and Afirma benign tests, and the high cost that currently limits their application outside the United States. Although longer follow-up is needed, recent postvalidation and clinical experience studies have demonstrated improved performance of both tests for indeterminate FNAC with Hürthle cell-dominant cytology,[110] in spite of the predominance of widespread chromosomal losses and mitochondrial DNA alterations in Hürthle cell carcinomas.[111,112]

ThyroPrint, a gene expression classifier based on interrogation of only 10 miRNAs, has also displayed good performance (sensitivity 96%, specificity 87%, and positive and negative predictive values of 78% and 98%, respectively).[113] Promising results have also been reported for a combination assay using miRNA classification (ThyraMIR) and next-generation sequencing mutation analysis (ThyGeNEXT) (positive predictive value 74%, negative predictive value 94%).[104] However, the assay has yet to be subjected to independent validation. ThyroSPEC is a cost-efficient matrix-assisted laser desorption/ionization–time of flight mass spectrometry-based mutation detection panel that detects the most prevalent 117 point mutations and 23 gene fusions in thyroid cancer.[107] All molecular diagnostic test except the ThyroSPEC molecular test require additional liquid FNAC material generated by dedicated FNAC passes in preserving solutions, whereas ThyroSPEC analyzes the residual liquid material or the FNAC material of a representative FNAC glass slide smear after routine FNAC.[107]

A systematic review of studies examining *RAS* mutations reported a range from 0% to 48% for the prevalence of *RAS* mutation in benign lesions, 0% to 68% for *RET/PTC* rearrangements, and 0% to 55% for *PAX8/PPARG* rearrangements in benign lesions.[114] Therefore, the presence of these biomarkers and the tremendous variation in reports of their prevalence in benign lesions suggests the need for caution when including these markers in diagnostic decisions. Further characterization of the importance of these markers, as well as newly discovered markers of thyroid malignancy, is required in order to avoid overtreatment of patients with benign thyroid tumors. However, the interpretation of these results is further complicated by the large interobserver for differentiating adenomatous nodules, thyroid adenomas, and minimally invasive FTCs.[84] This high rate of histopathological discordance hampers translational studies assessing the value of molecular markers that aim to improve presurgical diagnosis, because the histological reference for these studies can be ambiguous or discrepant. Therefore, it is likely that the current histology-based classification of thyroid tumors[1] will ultimately be complemented by molecular/genetic characteristics for a more accurate classification, akin to other endocrine tumors or other cancers.

The cost-effectiveness of molecular FNAC tests varies dramatically depending on the healthcare setting (for example, in a multidisciplinary tertiary care setting vs. a primary care setting), the cost of the test, the cost of a lobectomy, the risk of malignancy for the respective FNAC diagnosis, and the sensitivity, specificity, and negative and positive predictive values and accuracy and impact on clinical decision-making, and the quality of evidence reported for the respective molecular test. Consequently, the cost-effectiveness of molecular FNAC tests needs to be evaluated for each specific interdisciplinary diagnostic pathway setting, and end users need to perform independent studies on the basis of regional costs and population demographics and ultrasound and FNAC performance.[115] This was recently demonstrated by the first large patient cohort study before and after ThyroSeq implementation with 773 consecutive patients. It reported a doubling of AUS/FLUS and FN/SFN cytologies and an increase of the overall cost of care for patients with thyroid nodules.[116] This study did not include any information on ultrasound malignancy risk stratification and emphasizes again the importance of local outcome evaluations taking into account all building blocks of the diagnostic pathway for the characterization of a nodule.

KEY POINTS

- Thyroid nodule and thyroid cancer diagnostics should be organized as a pathway. Deficiencies for one of the diagnostic steps or expertise cannot be compensated for by (over)emphasizing any other step or expertise.
- As part of an integrated approach of careful clinical, ultrasound, and fine-needle aspiration cytology assessment with local outcome data, molecular testing may be able to improve diagnostic outcomes for thyroid nodules.

TREATMENT OF AUTONOMOUS THYROID NODULES

Antithyroid drugs, usually in combination with beta-blocking drugs, are the first-line treatment in all patients with overt thyrotoxicosis. Depending on the type of antithyroid drug, an initial dosage of 10 to 30 mg/day of methimazole, 20 to 60 mg/day of carbimazole, or 150 to 300 mg/day of propylthiouracil is recommended. Higher doses are associated with more frequent adverse effects (3%–12%) and will only result in marginally faster resolution of thyrotoxicosis. Furthermore, a trial of low-dose drug therapy (5–10 mg methimazole per day) may be justified in selected patients with symptomatic subclinical thyrotoxicosis.

While the purpose of antithyroid drug therapy is to render the patient euthyroid, there is, contrary to Graves disease, practically no spontaneous resolution of thyroid autonomy. This implies that, once thyroid autonomy becomes clinically manifest, one needs to either consider definitive treatment or choose long-term therapy with a thionamide in selected patients. However, benefits and risks of such “long-term” drug therapy have to be weighed against the potential advantages and limitations of definitive treatment.[83] Several ablative treatment options are available for TA and TMNG: thyroid surgery, radioiodine therapy, and thermal ablation techniques.

Surgery

The purpose of thyroid surgery is to cure thyrotoxicosis by removing all autonomously functioning thyroid tissue and other macroscopically visible nodular thyroid tissue. The extent of surgery is determined by preoperative ultrasound and, importantly, intraoperative morphologic inspection. For TA, hemithyroidectomy is usually adequate. In the case of TMNG, a subtotal, near-total, or total thyroidectomy is indicated. The advantages of surgery (removal of all nodular tissue, rapid and permanent resolution of thyrotoxicosis, and definite histologic diagnosis) have to be weighed against general (risk of anesthesia) and thyroid-specific side effects, the latter of which are largely dependent on the surgeon’s training and expertise (vocal cord paralysis ~1%, permanent hypoparathyroidism <1% for an experienced endocrine surgeon) (see Chapter 82). The incidence of postoperative hypothyroidism depends on the extent of thyroid resection.

While thyroid surgery is usually performed after euthyroidism has been achieved with antithyroid drug treatment, surgery is also advocated in patients with overt thyrotoxicosis who, prior to surgery, have had adverse side effects of a drug, or in patients with thyrotoxic storm who are refractory. Rapid control of severe thyrotoxicosis can be achieved by the administration of glucocorticoids, beta-blockers, and iodide in patients allergic to antithyroid drugs (see also Chapter 84).[83]

Radioiodine Therapy

Radioiodine therapy is widely used for treatment of thyroid autonomy and is highly effective in terms of eradicating thyrotoxicosis and reducing thyroid gland volume. The success rate for therapy has been reported to range between 85% and 100% in TA and up to 90% in TMNG. An average thyroid and/or nodule volume reduction of approximately 40% can generally be anticipated.[117]

To reduce the risk of exacerbation of hyperthyroidism, it has been recommended to render the patient euthyroid with antithyroid drugs prior to treatment. Usually, the antithyroid drug is discontinued at least 4 days before radioiodine therapy and resumed no sooner than 3 days afterward.[118] With large goiters (>80–100 mL), and especially with suspicion of malignancy, thyroid surgery is recommended. Different protocols have been suggested for therapy in benign thyroid disease. Some investigators prefer to administer a standard dose, e.g., 10 or 20 mCi (370–740 MBq) per thyroid gland, while others apply a certain activity per gram of thyroid tissue. Different algorithms exist for dose calculation, e.g., in Germany, dosage is mostly calculated according to the Marinelli formula, which takes into account the maximum radioiodine uptake. Advantages of radioiodine are its simplicity and, in many countries, its outpatient-based applicability. Disadvantages are the “time to euthyroidism” period (6 weeks to >3 months) during which drug therapy has to be continued and thyroid function monitored at 3- to 6-week intervals (Table 77. 3). Radioiodine treatment is contraindicated in pregnancy, and contraception is recommended for at least 6 months after receiving therapy.

Side effects of radioiodine treatment include transient local pain and tenderness. Significant exacerbation of thyrotoxicosis due to destructive thyroiditis is uncommon. In general, most studies have not shown an increased risk of thyroid cancer, leukemia, or other malignancies, reproductive abnormalities, or congenital defects in the offspring, in adults treated with radioiodine.[119] However, a more recent study has suggested a modest positive association with the risk of death from solid carcinomas, including breast cancer, in patients treated with radioiodine for hyperthyroidism,[120] and the safety in children remains controversial.[121]

Hypothyroidism after therapy for TMNG and TA usually develops insidiously. The prevalence of hypothyroidism depends on the extent of TSH suppression prior to therapy and the protocol applied, and, importantly, increases with the duration of follow-up. In a retrospective study of 346 patients with hyperfunctioning thyroid nodules, the occurrence of hypothyroidism was 7.6% at 1 year, 28% at 5 years, 46% at 10 years, and 60% at 20 years of follow-up.[122] These data emphasize the requirement of long-term monitoring of thyroid function in all patients receiving therapy.

Radioiodine treatment is considered safe and appropriate in nearly all types of hyperthyroidism, especially in older adult patients.[123,124] Generally, radioiodine therapy is thought to carry a lower rate of complications and a lower cost than surgery. This fact has led a number of centers to offer radioiodine therapy as the first choice of therapy in the majority of patients. In contrast to surgery, which cures nearly all patients and normalizes hyperthyroidism within a few days,[125] only 50% become euthyroid within 3 months of therapy, given that antithyroid drugs are not administered.[126] Twenty to forty percent need additional therapy, and even up to five treatment sessions will not cure all patients. In contrast, persistence of hyperthyroidism after surgery is rare.[125]

A summary of the advantages and disadvantages of the different treatments for TA and TMNG is shown in Table 77.4. For patients who refuse or are not suitable for surgery or radioiodine therapy, radiofrequency or laser ablation of the hot nodule is increasingly accepted as an alternative treatment option.[127]

Follow-Up

The long-term management of TA and TMNG patients is aimed at the detection and adequate treatment of thyroid dysfunction, prevention,

TABLE 77.3 Treatment Options for Patients with Toxic Multinodular Goiter

	Advantages	Disadvantages	Comments
Surgery	Significant goiter reduction Rapid achievement of euthyroidism Allows pathologic examination	Not all patients eligible Surgical mortality and morbidity a little higher than in nontoxic goiter Persistence or recurrence of hyperthyroidism Hypothyroidism*	Standard therapy for a large goiter or when rapid decompression is required Treatment of choice if radioiodine is not feasible
Antithyroid drugs	Easiest treatment option Mainly used at preparation for radioiodine or surgery	Lifelong treatment needed Very little chance of remission Adverse effects in approximately 5% Continuous goiter growth	Major indications are before thyroid surgery and before and after radioiodine, particularly in older adult patients and those with concurrent health problems Long-term treatment recommended only when surgery or radioiodine cannot be used
Radioiodine	Effective in rendering patients euthyroid and in reducing thyroid volume Most often outpatient Few subjective side effects	Only gradual reversal of hyperthyroidism Gradual reduction of the goiter Small risk for acute goiter enlargement Risk for thyroiditis: 3% Risk for transition into Graves disease: 5% Five-year risk for hypothyroidism: 15% Small risk for radiation-induced ophthalmopathy Treatment needs to be repeated in some	Standard therapy unless the goiter is very large (>100 mL). High-dose radioiodine (inpatient treatment) may be an option in those with a very large goiter not fit for or who decline surgery
Thermal ablation - Radiofrequency - Laser ablation	Alternative options to surgical treatment or radioiodine	In experienced hands, serious side effects are very rare	Mostly used for euthyroid nodules

*The percentage of patients affected depends on the extent of surgery.

TABLE 77.4 Treatment Options for Patients with Nontoxic Multinodular Goiter

Treatment	Advantages	Disadvantages	Comments
Surgery	Significant goiter reduction Rapid decompression of vital structures Allows pathologic examination	Not all patients eligible Postoperative hemorrhage (1%) Recurrent laryngeal nerve injury (1%–2%) Hypoparathyroidism (0.5%–5%) Hypothyroidism* and goiter recurrence* Postoperative tracheomalacia (rare) Risk rates are slightly increased in cases of large goiter, intrathoracic extension, or reoperation	Standard therapy for large goiters or when rapid decompression is required Total thyroidectomy should be considered to avoid goiter recurrence
Thyroxine	Outpatient Low cost May help prevent new nodule formation or goiter growth	Low efficacy Mainly impact on the perinodular volume Treatment, if lifelong and aimed at TSH suppression, could induce side effects caused by subclinical hyperthyroidism and inadvertent effects on bone and the heart	Its role on the wane due to possible adverse effects and low efficacy in reducing size Not recommended by the authors Low-dose treatment may help prevent growth
Radioiodine	Halving of thyroid volume within 1 year Improves inspiratory capacity in long term Most often outpatient Can be repeated successfully Few subjective side effects	Gradual reduction of the goiter Decreasing effect with increasing size Small risk for acute goiter enlargement Risk for thyroiditis: 3% Risk for transition into Graves disease: 5% One-year risk for hypothyroidism: 15%–20% Small risk for radiation-induced ophthalmopathy Treatment needs to be repeated in some Risk for radiation-induced malignancy unsettled	Has replaced surgery as the standard therapy in some European countries. Should be contemplated instead of reoperation and in those who decline or are not fit for surgery, also in case of a very large goiter (high-dose radioiodine) For data in relation to rhTSH-stimulated therapy, please see the text
Thermal ablation - Radiofrequency - Laser ablation	Alternative options to surgical treatment or observation alone for solid nodules, purely or predominantly cystic nodules that recur after aspiration and ethanol ablation, and those that have a residual solid component after such therapy	In experienced hands, serious side effects are very rare.	Only 20% and 38% show significant regrowth in the long term after radiofrequency ablation or laser ablation, respectively

*The percentage of patients affected depends on the extent of surgery.
TSH, Thyroid-stimulating hormone; *rhTSH,* recombinant human thyroid-stimulating hormone.

and detection of novel nodular thyroid disease, and, in the case of surgery, detection and treatment of postsurgical hypoparathyroidism. With radioiodine therapy, long-term follow-up for the development of hypothyroidism is mandatory.

TREATMENT OF EUTHYROID NODULES (SEE TABLE 77.3)

Nodular thyroid disease is very common, but most of these goiters do not cause significant symptoms and are best left untreated. Treatment may be indicated in the case of the following:

1. Large goiter or progressive growth of the entire gland or individual nodules
2. Signs of cervical compression
3. Overt or subclinical hyperthyroidism
4. Marked neck disfigurement or cosmetic complaints
5. Suspicion of thyroid cancer

In a number of clinical situations, a discrepancy is seen between clinical findings and patient complaints. In this context, the decision whether to treat can be more difficult.

There is no ideal treatment for goiter, and practice patterns differ quite widely. This is, for example, reflected by the fact that one third of clinicians would refrain from treating a patient with moderate discomfort due to a multinodular nontoxic goiter of 50 to 80 g, where malignancy has been ruled out.[13] Comparative studies of available options are sparse. Thus, treatment is not only a matter of goiter reduction. Patient satisfaction, the risks for hypothyroidism and goiter recurrence, and fear of overlooking a thyroid cancer, age, and comorbidities are all important factors that should be taken into account. It follows that the optimal treatment of toxic and nontoxic multinodular goiter is controversial, and the therapeutic approach must be individualized.

Iodine Supplementation

Some clinicians, particularly in Europe, use iodine supplementation for treatment of goiter.[13] In nodular goiter, iodine is no better than levothyroxine (LT4) suppression therapy for goiter reduction in comparative trials. In addition, the major hindrance for the use of iodine consists in the fact that a sudden increase of iodine intake may induce thyrotoxicosis in individuals with underlying thyroid autonomy.

Thyroid Hormone Treatment

Thyroid hormone therapy for suppression of pituitary TSH secretion has been widely used in nontoxic multinodular goiter. Although LT4 suppressive therapy is effective in reducing the volume of diffuse nontoxic goiters by up to 30%, there are few controlled studies in nontoxic multinodular goiter, in which sonography has been employed for objective size monitoring. In one study, 58% of patients had a significant (>13%) decrease in thyroid volume, but regrowth was seen after discontinuation of therapy.[128] In a randomized trial, Wesche and coworkers[129] found a median reduction of goiter volume in the radioiodine treated group of 38% and 44% after 1 and 2 years, while the corresponding values in the LT4-treated group were 7% and 1%, respectively, and nonsignificant. In a German study, LT4 in combination with elementary iodine supplementation resulted in a goiter volume reduction of only 7.9%, and a nodule volume reduction of 17.3% within 1 year, as compared with placebo.[130]

For volume reduction, the LT4 dose is often adjusted to reach a partly suppressed serum TSH level.[130] The consequence is subclinical hyperthyroidism, which may adversely affect the skeleton and the cardiovascular system.[131] Because lifelong therapy is probably needed to avoid goiter recurrence, and the natural history of the disease is progression toward hyperthyroidism due to autonomous function of the thyroid nodules, LT4 treatment may not be appropriate in many patients.[132] Based on the aforementioned considerations, LT4 treatment has been abandoned by many endocrinologists for this indication.[13]

Surgery

For a comprehensive overview of thyroid surgery, see Chapter 82. The goal of surgery is removal of all thyroid tissue with a nodular appearance, usually by a unilateral hemithyroidectomy and subtotal resection of the contralateral lobe. A bilateral subtotal resection cannot be recommended. Only extremely rarely is a thoracic approach necessary. Further resection is not usually recommended if the final pathologic evaluation incidentally reveals a unilateral cancer less than 1 cm in size. This rather frequent finding accounts for most cancers found in surgical series, the majority of which are of little, if any, clinical significance.[133] Macroscopically normal perinodular tissue often harbors microscopic growth foci, which explains the relatively high risk for recurrence in these patients.[134] In the case of a toxic nodular goiter, thyroid function is more rapidly normalized after surgery than after antithyroid drug therapy. Surgery leads to rapid decompression resulting in improved respiratory function, if affected presurgically.[135]

Not all patients are surgical candidates, but among those undergoing surgery, the surgical mortality rate is less than 1% in experienced centers. Disadvantages include the general risks and side effects of a surgical procedure. Specific risks include transient (6%) or permanent (2%) vocal cord paralysis, transient (6%) or permanent (5%) hypoparathyroidism, and postoperative bleeding (1%).[135] Others have found lower figures.[136] Complications are related to increasing goiter size and extent of the resection.[137] Novel techniques may reduce the operation time, postoperative pain, and length of hospital stay. Postoperative tracheomalacia, necessitating intubation, can occur after the removal of large goiters but is a rare complication. A matter of concern is the apparently high prevalence (7%–17%) of thyroid carcinomas in substernal goiters,[138] but this seemingly high frequency is probably influenced by selection bias.[139]

The long-term risk for hypothyroidism after subtotal resection of multinodular goiters is insufficiently described, but is approximately 10% to 20%, as reported for toxic multinodular goiters, and related to the extent of the resection. Recurrence of the nontoxic multinodular goiter is seen in 15% to 40% of patients with long-term follow-up.[13] Postoperative use of LT4 is preferred by many clinicians to avoid recurrence; but based on results from randomized trials, use of LT4 is generally not recommended, and neither is iodine.[13,132] A reoperation for the recurrent goiter results in a 3-fold to 10-fold increase in risk for permanent vocal cord paralysis or hypoparathyroidism.[136,137] Goiter recurrence can be completely avoided if a total thyroidectomy is carried out initially, an approach that does not have a higher complication compared with subtotal thyroidectomy if the intervention is performed by high-volume surgeons.[140]

Radioiodine Therapy

Besides being able to cure hyperthyroidism, radioiodine therapy can also be used for volume reduction. During the last 25 years, radioiodine therapy for symptomatic multinodular nontoxic goiter has therefore been introduced in a number of mainly European centers as a nonsurgical alternative to LT4 therapy. Thyroid volume reduction is of the same magnitude in toxic and nontoxic multinodular goiters, that is, approximately 40% after 1 year[126,129,141,142] and 50% to 60% after 2 years, without further reduction.[141,143] Sixty percent of this decrease is seen within 3 months of therapy.[141,142] In addition to a relief of compressive symptoms, radioiodine therapy also results in decreased tracheal compression, which can improve pulmonary function, particularly the inspiratory component.[142,144] If used for very large goiters, normalization of thyroid volume, as seen in diffuse toxic and nontoxic goiters, is rarely achieved, but symptoms are in most cases considerably improved, and patient satisfaction is high.[144] If a secondary increase in thyroid volume is seen, this should raise the suspicion of malignancy. Generally, therapy doses of 100 μCi (3.7 MBq) per gram of thyroid tissue corrected for 100% 24-hour therapy uptake have been given.[144,145] However, it has been questioned whether such dose adjustment is worthwhile,[123,145] and fixed doses are given in a number of centers if nuclear medicine regulations allow to do so.[123] The treatment can be repeated if further goiter reduction in a euthyroid patient is required.[141]

Radiation thyroiditis is seen in 3% within the first months of radioiodine therapy[124] and is easily treated with salicylates or corticosteroids. Another possible complication consists in "Graves-like autoimmune hyperthyroidism," which is seen in up to 5%. Rare cases of radioiodine therapy-induced Graves ophthalmopathy have also been reported. The presence of anti-TPO antibodies prior to radioiodine therapy is associated with an increased risk for this complication, which is most likely triggered by therapy related release of thyroid antigens and the appearance of TSHR antibodies typically 3 to 6 months after radioiodine therapy. This phenomenon can also be seen after surgical manipulation of the thyroid or after subacute thyroiditis. The condition is often self-limiting, but may necessitate therapy.

Although goiter enlargement caused by radioiodine therapy may be seen initially after treatment, there is usually no significant acute thyroid enlargement.[124,142,146] The risk for permanent hypothyroidism after therapy in multinodular goiters ranges from 14% to 58% within 5 to 8 years.[124] It occurs more commonly in patients with a small goiter and when anti-TPO antibodies are present. Radioiodine therapy, given for Graves disease for decades, is not thought to be followed by any clinically significant increased risk for cancer deaths,[119,124,147] although one study questions this view (see earlier).[148] Most patients treated are older than 50 years of age and are less susceptible to radiation-induced malignancy than young individuals. Data regarding radioiodine therapy in multinodular goiter are sparse, and in the case of nontoxic goiter, nonexistent. In a study by Ron and coworkers,[147] 1089 patients were treated for a toxic nodular goiter, and these individuals had a 31% increase in overall cancer mortality, nearly exclusively attributable to thyroid malignancy. However, a similar pattern was seen in patients not treated with radioiodine. Hence, the detection of a thyroid cancer in a nodular goiter after radioiodine therapy raises the question of whether malignancy in a nodule had been overlooked prior to radioiodine therapy.

In some European countries, radioiodine therapy has replaced surgery as the treatment of choice in most patients.[13,124] However, the optimal treatment modality remains to be established, ideally through comparative randomized trials, including data on effect, side effects, cost, and patient satisfaction.

The efficacy of radioiodine therapy in multinodular goiter is hampered by the irregular therapy uptake in the gland, and the relative goiter reduction is inversely correlated with the initial goiter size.[124,142] A high dietary iodine intake diminishes efficacy. Recombinant human TSH (rhTSH) has the potential of increasing the 24-hour radioiodine therapy uptake more than 4-fold, and the effect is inversely correlated to the initial thyroid radioiodine therapy uptake.[124,149-152] Moreover, pretreatment with rhTSH causes a more homogeneous distribution of radioiodine therapy within the nodular gland.[153] These properties of rhTSH are ideal in the context of therapy of multinodular goiter. Several studies, including two randomized double-blind trials,[124] have shown that rhTSH, in doses from 0.1 mg to 0.9 mg and administered 24 hours before radioiodine therapy, improves goiter reduction by 35% to 55% within 1 year, compared with radioiodine therapy without stimulation. RhTSH-augmented radioiodine therapy also results in reduced tracheal compression and an enhancement of the inspiratory reserve, as shown in a randomized trial.[154] Long-term follow-up studies have documented that the enhanced goiter volume reduction obtained with rhTSH-augmented therapy improves the reduction in goiter-related symptoms and reduces the need for additional therapy.[124] The administration of rhTSH may also permit the successful use of lower activities of radioiodine to achieve goiter reduction.[117,155] Indeed, in a randomized double-blind study,[155] it was demonstrated that an equivalent goiter reduction after radioiodine therapy can be obtained by a much lower thyroid dose if rhTSH prestimulation is used.[155,156] Although rhTSH stimulation has several attractive aspects for volume reduction in selected patients, it is important to emphasize that it forms an "off-label" treatment for multinodular goiter. RhTSH-augmented radioiodine therapy is generally well tolerated, particularly when using a dose of 0.1 mg or lower. A drawback of rhTSH-augmented radioiodine therapy is the fact that, in parallel with the improved goiter reduction, a higher frequency of hypothyroidism is encountered.[124] If rhTSH stimulation is used in order to lower the amount of the radioactive dose delivered to the thyroid gland, the risk for permanent hypothyroidism is comparable to that seen after radioiodine therapy alone.[155]

Nonsurgical Thermal Ablation of Thyroid Nodules

Thermal ablation has shown efficacy in the treatment of a spectrum of benign thyroid nodules in multiple studies. In benign nodules that cause pressure symptoms and/or cosmetic concerns, when balancing efficacy, side effects, and cost, both laser ablation and radiofrequency ablation are alternative options to surgical treatment or observation for solid nodules, purely or predominantly cystic nodules that recur after aspiration and ethanol ablation, and those that have a residual solid component after such therapy.[127,157] Only 20% and 38% show significant regrowth in the long term after radiofrequency ablation or laser ablation, respectively. In experienced hands, serious side effects are very rare. Thermal ablation for properly selected patients is widely used in some countries, but currently still more rarely used in others. Prior to thermal ablation, FNAC is warranted to characterize the nature of the nodule. Size and location, as well as operator experience, influence outcomes. Lesions that are located in the posterior and medial part of the thyroid may not be amenable to thermal ablation because of the proximity to the recurrent laryngeal nerve and the esophagus ("danger triangle"). Proper identification of patients who are most likely benefit from these localized therapies is key. There is no reason for any therapeutic intervention (thermal ablation or surgery) for sonographically visible nodules *per se* without local symptoms or cosmetic reasons.

Percutaneous ethanol injection therapy (PEIT) has been used for two decades in solitary hot, toxic, and even cold thyroid nodules.[158] The most convincing effect is seen in solitary thyroid cysts.[127] In centers with access to thermal ablation techniques, PEIT now generally plays a secondary role.

KEY POINTS

- Surgery remains the primary therapy in symptomatic patients with benign nontoxic goiter, and should be as complete as possible to avoid recurrence.
- Radioiodine can be used as a nonsurgical therapy option in benign nontoxic nodular goiter. Efficacy can be augmented by recombinant human thyroid-stimulating hormone prestimulation of iodine uptake.
- Thermal ablation has repeatedly shown efficacy in the treatment of a spectrum of benign thyroid nodules.

EPIDEMIOLOGY

Thyroid cancer is the fifth most common cancer in women, contributing 6.3% of the total number of new cases diagnosed in 2018. In the United States, the estimated incidence of new cases of thyroid carcinoma for 2020 was 52,890, representing 2.9% of all new cancer cases. The rate of death from thyroid cancer has been stable at 0.4%, suggesting that the increased incidence is primarily the result of diagnosis of subclinical, indolent tumors. The median age at diagnosis is approximately 45 to 50 years old, and differentiated thyroid carcinoma (DTC) is diagnosed two to four times more frequently in women than in men.[1]

The incidence of thyroid cancer was relatively stable until the early 1990s, after which it increased substantially.[2] Since 1975, the incidence of thyroid cancer has nearly tripled, from 4.9 to 14.3 per 100,000 individuals (absolute increase, 9.4 per 100,000). Almost the entire increase was attributable to papillary thyroid cancer (PTC), from 3.4 to 12.5 per 100,000 (absolute increase, 9.1 per 100,000),[2] suggesting that the increase is the result of diagnosis of subclinical, indolent tumors. The size distribution of detected thyroid cancer has shifted toward smaller lesions. In 1988 to 1989, 25% of detected thyroid cancers were 1 cm or smaller. In the most recent data (2008–2009), 39% were 1 cm or smaller.[2]

Autopsy series have shown that up to 6% of thyroid glands in autopsied adults in the United States, and over 20% in Japan, also harbor microscopically detectable foci of thyroid carcinoma, probably of no clinically significance.[3,4]

Compared with other malignancies, thyroid cancer has a high rate of cure with very high long-term survival rates, such as 98.3% 5-year relative survival.[1] For PTC, the most frequent thyroid malignancy, the 5-year relative survival rate for localized PTC is nearly 100%, for regional PTC is 99%, for patients who present with distant is metastasis is 76%, and for all Surveillance, Epidemiology, and End Results (SEER) stages combined is near 100%.[5]

KEY POINTS

- The incidence of thyroid cancer has nearly tripled, from 4.9 to 14.3 per 100,000 individuals. Almost the entire increase was attributable to small papillary thyroid cancer. The rate of death from thyroid cancer has been stable at 0.4%, suggesting that the increased incidence is primarily the result of diagnosis of subclinical, indolent tumors.
- The median age at diagnosis of thyroid cancer is approximately 45 to 50 years old, and differentiated thyroid cancer is diagnosed two to four times more frequently in women than in men.
- Compared with other malignancies, thyroid cancer has a high rate of cure with very high long-term survival rates, such as 98.3% 5-year relative survival.

PATHOLOGY

Papillary and follicular carcinomas are the two most common subtypes of thyroid cancer, referred to as DTC.

The fourth edition World Health Organization (WHO) Classification of Tumors of Endocrine Organs was published in 2017, in which the new thyroid tumor classification was included.[6] Several modifications to follicular cell tumors were made (Table 78.1). The major revisions were: i) the introduction of borderline tumors (uncertain malignant potential [UMP] and noninvasive follicular thyroid neoplasm with papillary-like nuclear features [NIFTP] and hyalinizing trabecular tumors) in the thyroid tumor classification; ii) PTC comprising 15 variants, and a new (hobnail) histologic variant being included; iii) follicular thyroid carcinoma (FTC) being subdivided into three prognostic groups: minimally invasive (capsule invasion only), encapsulated angioinvasive, and widely invasive; iv) Hurthle/oncocytic cell tumors being separated from follicular adenoma (FA)/FTC in an independent chapter, as it has a different genetic profile from those of the other types of thyroid cancer; v) the diagnostic criteria of poorly differentiated carcinoma being more precisely defined and adopting the Turin consensus criteria; vi) emphasizing the prognostic value of genetic markers, such as BRAFV600E and telomerase reverse transcriptase (*TERT*) promoter mutation, in thyroid carcinoma of follicular cell origin; and vii) emphasizing the examination of the entire capsule to identify or exclude invasiveness in encapsulated thyroid tumors.[7]

Papillary Thyroid Carcinoma Variants

Fifteen variants of PTC were listed in the most recent WHO classification of thyroid tumors (Table 78.2).[6]

Conventional/Classic Type. PTC is a malignant epithelial tumor demonstrating evidence of follicular cell differentiation and a set of distinct nuclear features (nuclear folding, increased mitoses, and hyperchromasia of the nucleus; the cell nuclei have a ground-glass or "cat's eye" appearance and intracellular inclusions are common) (Fig. 78.2).

TABLE 78.1 Modified from WHO Classification of thyroid tumors (4th edition – 2017)

1. Papillary thyroid carcinoma (PTC) variants:
    - Conventional / classic variant
    - Papillary microcarcinoma
    - Encapsulated PTC – applicable to fully encapsulated classic PTC
    - Diffuse sclerosing variant
    - Tall cell variant
    - Columnar cell variant
    - Cribriform-morular variant
    - Hobnail variant – new entity

PTC
- PTC with fibromatosis/fascitiis-like stroma
- Solid/trabecular variant
- Oncocytic variant
- Spindle cell variant
- Clear cell variant
- Warthin like variant

(note that variants diffuse sclerosing, tall cell, columnar cell, hobnail and solid/trabecular are so-called aggressive variants).

2. Follicular thyroid carcinoma (FTC) groups:
    - Minimally invasive FTC – capsular invasion only
    - Angioinvasive FTC
    - Widely invasive FTC – grossly invasive
3. Hürthle cell (oncocytic) tumors as a separate entity:
    Include Hürthle cell adenoma and Hürthle cell carcinoma, previously classified as oncocytic variant of follicular adenoma and FTC. The term "Hürthle" is favored over "oncocytic"
4. Poorly differentiated thyroid carcinoma:
    Turin criteria were adopted

PTC usually does not have a true capsule (invades surrounding normal tissue, invades blood and lymph channels). Papillae, invasion, or cytological features of PTC are required according to the 2017 WHO classification (fourth edition).[6] After publication of the 2017 WHO classification, the identification of definite invasion, as well as the demonstration of well-developed nuclear features and true papillae, have become essential components in the diagnosis of PTC.[6] These criteria have become stricter to reduce overdiagnosis of indolent tumors.[2]

Papillary cancer is often multicentric and bilateral.[8,9] Lymphatic spread within the thyroid is the likely reason for the high frequency of multifocality of the tumor. Vascular invasion and distant metastases (most often to the lung and bone) are rare and account for 2% to 5% of cases.

Papillary Microcarcinomas. Papillary microcarcinomas (PMCs) are tumors less than or equal to 1 cm in diameter. In some series, PMC comprise more than half of the surgically treated patients.[2,10] They may have features of a classic papillary carcinoma, or they may appear as unencapsulated sclerotic nodules of a few millimeters, infiltrating the surrounding thyroid. Most of these small tumors are not biologically significant, considering the much lower incidence of clinically recognized cancer. Less than 1% of patients with PMC have more aggressive disease identified by the presence of distant metastases at presentation.

Encapsulated Papillary Thyroid Cancer—Fully Encapsulated Classic Papillary Thyroid Cancer. This variant is classic PTC completely surrounded by a fibrous capsule that may be intact or only focally infiltrated by the carcinoma.[6] The prognosis is excellent, with close to a 100% survival rate, even though regional lymph node metastases may be present.[11]

Follicular Variant Papillary Thyroid Cancer. Follicular variant papillary thyroid cancer (FVPTC) has the basic histologic structure of follicular cancers, but the characteristic nuclei of papillary cancers. These constitute the "follicular variant" of papillary cancer, and behave more or less as do other papillary cancers (low-grade tumors).[12] The variant was subclassified into encapsulated and nonencapsulated (infiltrative) variants. The encapsulated FVPTCs were further divided into invasive and noninvasive. The noninvasive encapsulated follicular variant of PTC was reclassified from carcinoma to noninvasive follicular thyroid neoplasm with papillary-like nuclear features (NIFTP).[13] Those tumors with definite invasion remain in the category of invasive encapsulated FVPTC.

A new definitions of FVPTC, NIFTP, and well-differentiated tumor (WDT)-UMP were incorporated into the fourth edition of the WHO classification.

TABLE 78.2 Inheritance, Gene Involved, and Risks of Familiar Cancer Syndromes for Developing Thyroid Cancer

Disease	Histological Type	Gene Mutation	Location	Incidence of Thyroid Cancer	Pathological Variant of PTC
FAP and Gardner syndrome	PTC	*APC* tumor suppressor gene	5q21	2%–12%	Cribiform-morular classical variant
Cowden syndrome	FTC, PTC, C-cell hyperplasia	*PTEN* tumor suppressor gene	10q23.2	>10%	
Carney complex	FTC, PTC	*PRKAR1-x*	2p16 17q22-24	60% 4%	
Werner syndrome	FTC, PTC, ATC	*WRN* gene	Spl1-pi 2	18%	

PTC, Papillary thyroid cancer; *FAP,* familial adenomatous polyposis; *APC,* adenomatous polyposis; *FTC,* follicular thyroid cancer; *PTEN,* phosphate and tensin; *PRKAR1-x,* protein kinase A regulatory subunit type 1-alpha; *ATC,* anaplastic thyroid cancer; *WRN,* Werner.
From Son EJ, Nosé V. Familial follicular cell-derived thyroid carcinoma. *Front Endocrinol (Lausanne).* 2012;3:61.

		Capsular/vascular invasion		
		Present	Questionable/incomplete	Absent
PTC type nuclear features	Present	Follicular variant PTC	Well-differentiated tumor of uncertain malignant potential (WDT-UMP)	Noninvasive follicular thyroid neoplasm with papillary-like nuclear features (NIFTP)
	Questionable/ incomplete	Well-differentiated carcinoma, NOS		
	Absent	Follicular carcinoma	Follicular tumor of uncertain malignant (FT-UMP)	Follicular adenoma

Fig. 78.1 Red indicates malignant tumors, green for borderline tumors, and light blue for benign follicular adenoma.

Noninvasive variants of FVPTC and WDT-UMP were reclassified as NIFTP. Questionable/incomplete capsular invasion of FVPTC was merged into WDT-UMP (Fig. 78.1).[14]

Diffuse Sclerosing Variant Papillary Thyroid Cancer. This variant is rare and is estimated to account for up to 6% of all PTCs.[15] The typical histopathological characteristics include classic nuclear features of PTC, diffuse stromal fibrosis, dense lymphoid infiltration, squamous metaplasia, and abundant psammoma bodies.[16]

Diffuse sclerosing variant papillary thyroid cancer (DSVPTC) is found most often in children and young adults. Tumors are often multifocal and have more extrathyroidal extension (ETE) compared with classical PTC. Extensive lymphocytic infiltration of the thyroid gland is often found, and lymph node metastasis is present in up to 100% of cases. Disease recurrence is also more common in patients with DSVPTC than in those with PTC.[17] In a large multicenter study, the risk of recurrence was significantly higher in DSVPTC patients than for all other PTC patients (hazard ratio [HR] 8.5 [5.2; 13.9], $P < 0.0001$), but not when compared with high-risk PTC (HR 1.1 [0.6; 2.2], $P = 0.5$). Overall, the cancer-related death rate was lower in non-DSVPTC patients than in DSVPTC patients (1.8% vs. 10%, $P = 0.05$).[18]

Tall Cell Variant Papillary Thyroid Carcinoma. These tumors have a papillary pattern (similar nuclear features of PTC), and the cells are tall and columnar in shape, with a granular, eosinophilic cytoplasm.[19] According to the WHO classification, tall cell variant papillary thyroid carcinoma (TCVPTC) is a PTC composed of cancer cells that are two to three times taller than they are wide. The most recent WHO classification also defined that tall cells must account for more than 30% of all tumor cells for a diagnosis of the tall-cell variant (revised from the previous definition of more than 50% by the 2004 WHO classification).[6]

A review of the literature by Silver at al. found that the incidence of TCVPTC ranged between 5% and 11% of PTCs.[20] Several studies have shown that TCVPTC tumors had more aggressive features with advanced tumor stage at diagnosis, including higher incidence of ETE, vascular invasion, larger primary tumor size, lymph node metastases, and older patient age.[21-22] Also, the prevalence of *BRAF* and *TERT* mutations in TCVPTC is significantly higher than that in classical PTC. In a study performed by Dettmer et al., 7% of TCVPTCs had a *TERT* promoter mutation, whereas 61% demonstrated a *BRAF* mutation.[23] Patients had poorer prognosis, with higher overall mortality at 10 years (up to 22% for patients with TCVPTC, compared with 8.6% for PTC).

A large population-based study by Kazaure et al. found that rates of distant metastases in patients with TCVPTC were 2.6% higher than those for patients with PTC. Disease-specific mortality rates at 5 years were also higher for TCVPTC, at 6.4% compared with 2.3% for patients with PTC ($P < 0.001$).[24]

Columnar Cell Variant. Columnar cell variant is a rare subtype of PTC accounting for 0.15% to 0.2% of all PTCs.[25] It has tall-cell morphology without the typical nuclear cell features of PTC.[26] The prognosis is poor when it exhibits ETE, but if the tumor is encapsulated, it has indolent clinical behavior.[27]

Cribiform-Morular Variant. This variant can be sporadic, but more than half of cases occur in patients with familial adenomatous polyposis (FAP) syndrome and *APC* gene alteration.[28] The American Thyroid Association (ATA) guidelines recommend that pathologists specifically note this variant, which could lead clinicians to consider genetic counseling referral.[29] This variant usually develops multiple encapsulated nodules in the thyroid gland, and in general it has a better prognosis, with lower frequency of lymph node metastases, recurrence rates, and distant metastases.[30]

Hobnail Variant. This variant is a new entity first introduced in 2017 to the WHO classification of thyroid tumors.[6] It is a rare subtype, with a frequency of 0.15% to 0.2% of all PTCs. It is a moderately differentiated PTC with aggressive behavior and poor prognosis.[31] This variant consists of complex papillary structures covered by follicular cells that contain eosinophilic voluminous cytoplasm and large apical nuclei ("hobnails"). Hobnail variant PTC was defined with a cutoff of greater than 30%, as some hobnail features could be seen in classic PTC and DSVPTC.[32]

Solid/Trabecular Variant. This variant is diagnosed when all or nearly all of the tumor has a solid, trabecular or insular growth pattern with nuclear features of PTC.[6] This variant was frequently seen in pediatric patients following the Chernobyl nuclear accident,[33] and it was referred to as a nonaggressive variant in children. However, adults with this same variant have a slightly higher risk of recurrence and cause-specific mortality (10% at 10 years).[34]

FOLLICULAR THYROID CARCINOMA

Follicular carcinoma is typically a solitary, encapsulated nodule in the thyroid. The distinction between follicular adenoma and follicular carcinoma depends on the presence of capsular/vascular invasion. The diagnosis of malignancy is based on the demonstration of unequivocal vascular invasion and/or capsular invasion and the lack of typical nuclear features of PTC. Examination of the full capsule of the tumor is necessary to exclude the presence of invasion, therefore FTC cannot be distinguished from benign adenoma on fine-needle aspiration cytology only (Fig. 78.5). The major driver mutation is in the *RAS* gene (RAS-like tumors).[35] The 2017 WHO classification subdivided FTCs, depending on the degree of invasiveness, into three groups: (i) minimally invasive FTC (capsular invasion only), which represent more than 50% of cases, (ii) angioinvasive FTC, and (iii) widely invasive FTC (grossly invasive).[6] This classification highlights the importance of vascular classification in risk stratification of thyroid carcinomas.[36] FTC invades blood vessels but rarely invades lymphatics. Metastases are spread hematogeneously to the lungs, bones, and, less commonly, the brain and liver.[37]

HURTHLE CELL (ONCOCYTIC) TUMORS

The 2017 WHO classification has described these tumors as a separate entity, given their unique biological and clinical features and different genetic profile from FTC.[38] This entity includes Hurthle cell adenoma and Hurthle cell carcinoma (HCC). These tumors are composed of cells derived from the follicular epithelium and characterized by large size with abundant granular, eosinophilic cytoplasm resulting from the large number of mitochondria inside the cells. The cells have large nuclei and prominent nucleoli. Hurthle cells can be found in papillary carcinomas and in other benign conditions such as Hashimoto thyroiditis, benign nodules, and hyperthyroidism.

A diagnosis of HCC is based on the presence of capsular and vascular invasion, similar to FTC.[39]

POORLY DIFFERENTIATED THYROID CARCINOMA

In the new WHO classification, poorly differentiated thyroid carcinoma (PDTC) was more precisely defined with the Turin consensus criteria: (i) a diagnosis of carcinoma of follicular cell origin by conventional criteria (presence of invasion and/or metastasis); (ii) the presence of solid/trabecular/insular growth over more than 50% of the tumor area; (iii) the absence of PTC-N (nuclear features); and (iv) at least one of the following three features: convoluted nuclei (dedifferentiated nuclear feature of PTC), mitotic activity more than three per 10 high-power fields, or tumor necrosis.[40] PDTC occupies an intermediate position between differentiated (PTC and FTC) and anaplastic thyroid cancer, both histologically and clinically. Patients usually present with advanced stage at diagnosis, low radioactive iodine avidity, and frequent metastatic spread.[41]

KEY POINTS

- The fourth edition of the World Health Organization (WHO) Classification of Tumors of Endocrine Organs was published in 2017 and listed 15 variants of papillary thyroid carcinoma (PTC).
- PTC is often multicentric and bilateral. Lymphatic spread is common, while vascular invasion and distant metastases are rare.
- The noninvasive encapsulated follicular variant of PTC was reclassified from carcinoma to noninvasive follicular thyroid neoplasm with papillary-like nuclear features, and is now considered a precancerous lesion.
- The prevalence of *BRAF* and *TERT* mutations in tall cell variant PTC is significantly higher than that in classical PTC, conferring poorer prognosis with higher overall mortality.
- The distinction between follicular adenoma and follicular carcinoma depends on the presence of capsular/vascular invasion. Examination of the full capsule of the tumor is necessary to exclude the presence of invasion; therefore, follicular thyroid carcinoma (FTC) cannot be distinguished from benign adenoma on fine-needle aspiration cytology only. The major driver mutation is in the *RAS* gene (RAS-like tumors). FTC invades blood vessels but rarely invades lymphatics.
- The 2017 WHO classification has described these tumors as a separate entity, given their unique biological and clinical features and different genetic profile from FTC.

CAUSES

Somatic Gene Alterations

The main genes that play a role in cancer are oncogenes and tumor suppressor genes. Protooncogenes are genes that normally help cells grow when growth is needed. When a protooncogene mutates, whether by rearrangements, insertions/deletions, point mutations, or copy number alterations, it becomes an active oncogene and confers a growth advantage to the cell, eventually leading to malignant transformation. Another possible cause is the loss of a tumor suppressor gene. In this case, the malignant transformation occurs when these genes are inactivated.

Thyroid carcinoma is a genetically simple neoplasm with a low number of genetic alterations. It is one of better-characterized malignancies where more than 90% of cases have a driver mutation or gene fusion identified.[42] In well-differentiated thyroid cancer, driver gene mutations are generally mutually exclusive (one per tumor). Less well-differentiated thyroid cancers acquire additional genetic alterations as late events.[43] The most common initiating alterations in thyroid cancer are *BRAF* and *RAS* point mutations and *RET/PTC*, *NTRK*, and *PAX8/PPARg* chromosomal rearrangements, while *TP53* inactivation, *TERT* promoter mutations, and alterations in the PI3 kinase (PI3K) pathway are later events.

A comprehensive investigation of the genomic landscape of PTCs, the most common thyroid malignancy, was reported by The Cancer Genome Atlas Network (TCGA Network). Investigators of this group interrogated nearly 500 PTCs comprising mostly well-differentiated, low- to intermediate-risk cases.[44] These well-differentiated tumors were found to have a low frequency of somatic alterations, with the majority harboring mutually exclusive activating mutations in *BRAF* (60%) and *RAS*-family genes (13%), as well as fusion oncoproteins, primarily involving receptor tyrosine kinases (RTKs) such as *RET* (6%), *NTRK1* or *NTRK3* (2%), and *ALK* (1%). Distinct signaling and transcriptomic consequences were observed between BRAFV600E-like tumors, which showed higher mitogen-activated protein kinase (MAPK) transcriptional output and lower expression of genes involved in iodine metabolism, and RAS-like tumors, which had lower MAPK signaling and comparatively preserved expression of iodine-related genes.

BRAF-like tumors demonstrate a papillary growth pattern (conventional and tall cell variants), and have BRAFV600E mutations and rearrangement of the *BRAF*, *RET*, and *MET* genes. RAS-like tumors exhibit a follicular growth pattern with a distinct tumor capsule in more than 80% of cases, and have mutations in the *RAS*, *EIF1AX*, and *PTEN* genes, and rearrangement of the *PPARG*, *FGFR2*, and *THADA* genes. *TERT* promoter mutations at low frequency (<10%) and gene fusions of *ALK*, *NTRK1*, and *NTRK3* occur in both molecular groups.[43]

MAPK and PI3K-AKT are two main signaling pathways involved in thyroid carcinogenesis. The MAPK pathway, which is primarily involved in development of PTC, is commonly activated through point mutations in *BRAF* or *RAS*, as well as *RET/PTC* rearrangements. The PI3K-AKT pathway, which is associated with development of FTC, is activated through point mutations in *RAS*, *PIK3CA*, *AKT1*, and *PTEN*. Concurrent activation of both pathways is more frequent in more aggressive tumors.[45]

The most frequent mutational event in DTC is point mutations in the *BRAF* gene. This mutation is associated specifically with PTC, with a frequency of nearly 46%.[44] The presence of this mutation is associated with somewhat more aggressive disease (ETE, lymph node metastases), older age, and classic PTC or TCVPTC histology.

The *RAS* oncogene plays a fundamental role in human tumorigenesis. Activating mutations in its three protooncogenes—*HRAS*, *KRAS*, and *NRAS*—are found in nearly all human cancers, including thyroid cancer. Mutations in *RAS* genes occur, on average, in 30% to 45% of FTCs, 30%

to 45% of FVPTCs, 20% to 40% of PDTCs, and rarely in classical PTC. *RAS* mutations also occur in 20% to 25% of follicular thyroid adenomas. DTCs harboring *RAS* mutations alone have an excellent prognosis. Tumor aggressiveness is higher for thyroid cancers harboring *RAS* mutations and additional oncogenic mutations such as *TERT* promoter mutations, alterations of the PI3K pathway, and TP53 inactivation.[46]

The *RET* protooncogene encodes a cell membrane receptor tyrosine kinase. *RET* is highly expressed in thyroid parafollicular or C cells but not in follicular cells, where it can be activated by a chromosomal rearrangement known as the *RET/PTC* rearrangement. The two most common rearrangement types, *RET/PTC1* and *RET/PTC3*, account for most rearrangements found in thyroid cancer.[47] To date, there are more than 50 known rearrangements of *RET* in thyroid, lung, and other cancers. Although *RET/PTC* has been detected in some adenomas and other benign thyroid lesions, clonal *RET/PTC* (i.e., rearrangement that is found in a significant proportion of cells within the tumor) is reasonably specific for PTC and it is found in approximately 10% to 20% of adult sporadic papillary carcinomas. *RET/PTC1* is the most common rearrangement type (comprising up to 60%–70% of all positive cases). Tumors harboring *RET/PTC1* have a very low probability of progression to poorly differentiated and anaplastic carcinomas.[48] *RET/PETC3* is the most prevalent rearrangement in a cohort of papillary carcinomas that developed in children within 10 years of exposure to radiation after the Chernobyl accident. *RET/PTC* rearrangements occur with higher incidence in patients with a history of radiation exposure (50%–80%) and in papillary carcinomas in children and young adults (40%–70%). Papillary carcinomas with *RET/PTC* rearrangements typically present at younger age and have classic papillary histology and a high rate of lymph node metastases.[49]

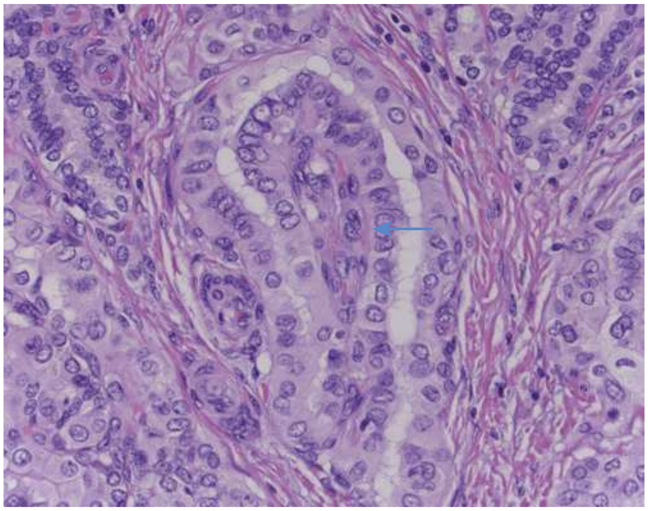

Fig. 78.2 **Classical papillary thyroid carcinoma (PTC).** A true papillary structure is present (fibrovascular core indicated with arrow) and the nuclei show enlargement, nuclear crowding and overlapping, and open pale chromatin. (Courtesy of Dr. Carrie Marshall)

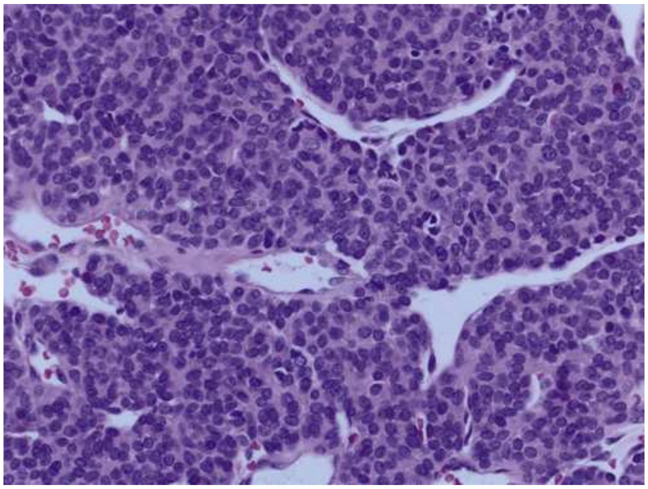

Fig. 78.4 **Poorly differentiated thyroid carcinoma.** The tumor is demonstrating a solid architectural pattern (nested/insular and trabecular architecture are also seen in poorly differentiated thyroid carcinoma) with nuclear crowding and overlapping. The tumor nuclei do not show the open and pale chromatin of papillary thyroid carcinoma. Tumors can have either round and uniform nuclei as demonstrated in this image, or have convoluted nuclear membranes. Mitotic figures and areas of necrosis are features of this diagnosis (not shown in this image). (Courtesy of Dr. Carrie Marshall)

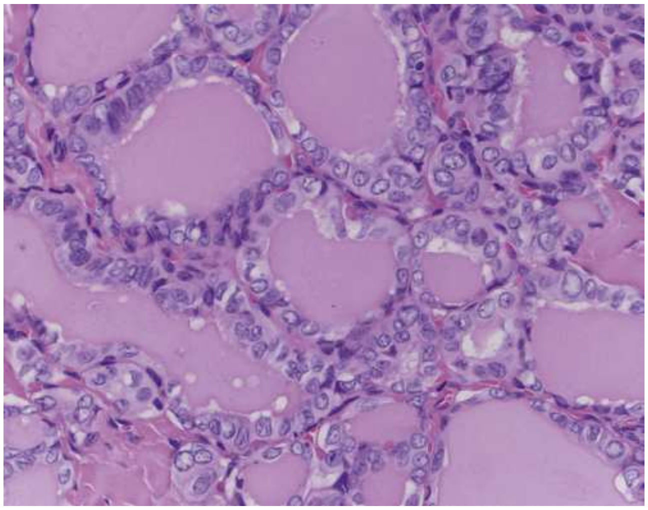

Fig. 78.3 **Follicular variant papillary thyroid cancer.** The tumor cells are arranged in follicles surrounding colloid, and no papillary structure are present. The nuclei show features that are diagnostic of papillary thyroid carcinoma (nuclear enlargement, nuclear crowding and overlapping, and open pale chromatin). (Courtesy of Dr. Carrie Marshall)

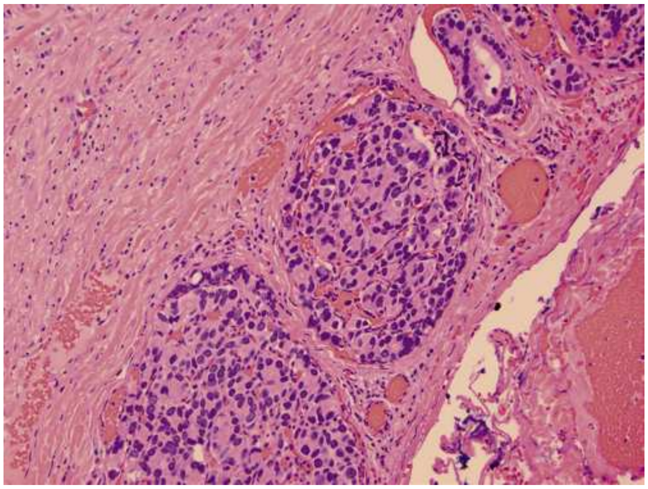

Fig. 78.5 **Follicular thyroid carcinoma with vascular invasion.** The rounded aggregates of microfollicles demonstrate thin-walled vascular spaces invaded by follicular thyroid carcinoma. The nuclei lack the characteristic changes of papillary thyroid carcinoma (pale and open chromatin, nuclear grooves, or nuclear pseudoinclusions). (Courtesy of Dr. Carrie Marshall)

The *PAX8/PPARγ* rearrangement is found in 30% to 40% of conventional-type follicular carcinomas and with lower prevalence in oncocytic carcinomas. Tumors harboring *PAX8/PPARγ* tend to present at a younger age and be smaller in size, and more frequently have vascular invasion. This rearrangement is also found in the follicular variant of papillary carcinoma, with a reported prevalence of less than 5% in most populations. This rearrangement can also be found in a small proportion (2%–13%) of follicular adenomas and Hurthle cell tumors. Detection of *PAX8/PPARγ* rearrangement in a follicular lesion is not fully diagnostic for malignancy by itself, but if exhaustive examination is performed by the pathologist, vascular or capsular invasion is frequently seen.[50]

Other somatic alterations found in PTC include *NTRK* rearrangement. It is found in fewer than 5% of papillary carcinomas in most studies. At least three types of the rearrangement exist, formed by fusion of the *NTRK1* gene to different partners.[51]

EIF1AX is mutated in only 1% of PTCs, largely occurring in a mutually exclusive manner with *BRAF* and *RAS*. *EIF1AX* mutations are predictive of worse survival in PDTCs.[43]

Progression of DTC to higher-grade cancer is associated with the accumulation of genetic alterations in other genes, such as *TP53*, *PIK3CA*, *AKT1*, *CDKN2A/CDKN2B*, and the *TERT* promoter[52] (Fig. 78.6).

TERT promoter mutations are highly prevalent in advanced thyroid cancers, particularly those harboring *BRAF* or *RAS* mutations.[52] Acquisition of a *TERT* promoter mutation could extend survival of BRAF- or RAS-driven clones and enable accumulation of additional genetic alterations leading to disease progression.[53] BRAF mutation alone is a weak independent predictor of tumor aggressiveness, and *TERT* promoter mutation alone carries a modest increased risk of recurrence and reduced survival, while both mutations together carry a significant risk of poor outcome.[54,55] An elegant mechanism of increased MAPK signaling through the *BRAF* mutation causing increased expression of GA-binding protein B, together with increased binding of GA-binding protein A to the mutated *TERT* promoter, leads to increased *TERT* expression and tumor aggressiveness, known as the "oncogenic duet."[56]

HCCs were not included in the CGA thyroid cancer study, which focused solely on PTCs. Although HCC traditionally has been classified as a subtype of FTC, emerging genomic data have validated the long-held idea that HCCs are distinct from other DTCs. A study by Ganly et al. revealed that the mutational profile of HCCs was very different from that of other types of well-differentiated thyroid cancer, such as PTC and FTC. There were no *BRAF* mutations (present in 62% of PTC), and the frequency of *NRAS* mutation was much lower than that of FTC. Genes important in PDTCs, such as TP53, *TERT* promoter, *PTEN*, *PIK3CA*, and *ATM*, were identified in the HCC cohort, but at a lower frequency.[57] This study also showed that HCCs are characterized by a high rate of somatic mitochondrial mutations (71% of HCCs) that may underlie the mitochondrial dysfunction that is the hallmark of this malignancy.

In summary, the most common oncogenic drivers in thyroid cancer include *BRAF* and *RAS* point mutations and *RET/PTC* and *PAX8/PPARγ* rearrangements. These nonoverlapping genetic alterations are found in more than 70% of PTCs and FTCs. These molecular alterations can be detected in surgically resected samples and fine-needle aspiration samples from thyroid nodules and can be of significant diagnostic, prognostic, and therapeutic utility.[47]

Germline Genetic Factors

Well-differentiated thyroid cancer accounts for 95% of thyroid malignancies, and approximately 5% of these patients will have familial disease. Such familial follicular cell-derived carcinomas are divided into two clinicopathological groups. The large majority of familial cancers (primarily papillary) occur as isolated, nonsyndromic, PTC, in which no predisposing oncogene has been detected. Familial nonmedullary thyroid carcinoma (FNMTC) syndrome is diagnosed when three or more family members have nonmedullary thyroid cancer in the absence of other known associated syndromes. This form of familial cancer has been reported in 3% to 10% of patients in different series.[58] Papillary thyroid carcinoma in FNMTC has a well-documented predisposition

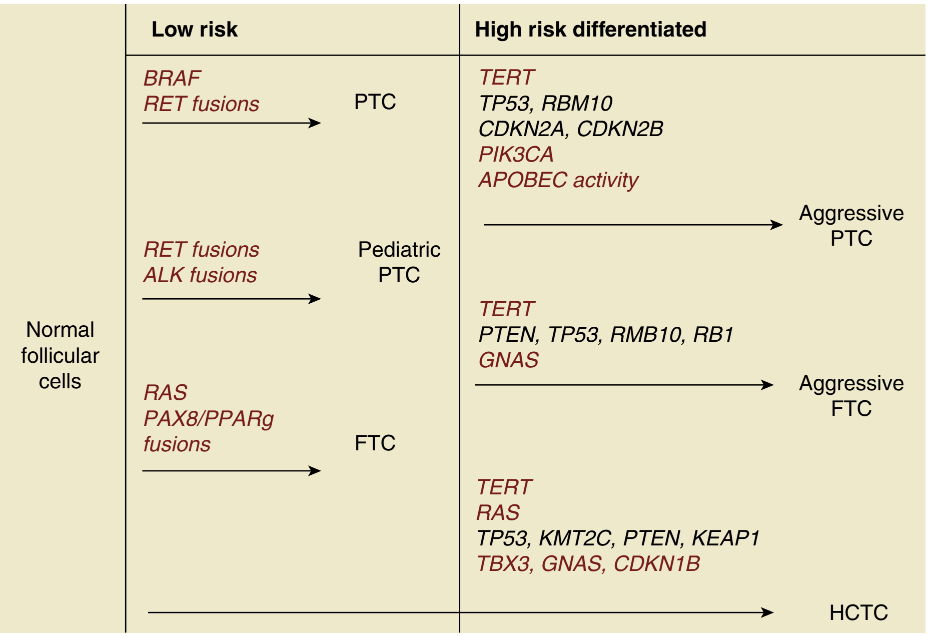

Fig. 78.6 Genetic evolution of thyroid cancer. Genetic alterations causing an increase in protein activity (activating point mutations, fusions and gene amplifications) are highlighted in red while loss-of-function mutation and copy number losses are shown in black. *PTC,* papillary thyroid carcinoma; *FTC,* follicular thyroid carcinoma; *HCTC,* Huthle cell thyroid carcinoma.

to multicentric disease, bilateral disease, local invasion, ETE, lymph node metastases, recurrence, and specific histology.

The syndromic-associated group includes FAP/Gardner syndrome, Cowden syndrome (PTEN-hamartoma tumor syndrome), Carney complex type 1, Pendred syndrome, and Werner syndrome.[59] The inheritance, gene involved, and risks of familial cancer syndromes for developing thyroid cancer are shown in Table 78.2.[60]

Familial adenomatous polyposis is inherited as an autosomal dominant trait caused by a germline mutation in the adenomatous polyposis coli (*APC*) gene. Patients typically have thousands of adenomas that are primarily located in the colon and rectum. PTC is one of the extracolonic manifestations of FAP. Young women with FAP are at particular risk of developing thyroid cancer, with a risk approximately 160 times higher than that of individuals without FAP. Among patients with FAP who have synchronous PTC, over 90% of these cases have been reported to cribriform-morular variant. Patients with cribriform-morular variant PTC should be evaluated for FAP. The ATA recommends that pathologists specifically comment on the cribiform-morular variant to aid in identifying these potential FAP patients.[29] This form of PTC is typically bilateral, presents at a younger age, and is 10 times more common in female patients with FAP. In contrast to conventional PTC, cribriform-morular variant PTC rarely metastasizes and carries a relatively benign prognosis.[62] Cowden syndrome is an autosomal dominant disorder caused by a germline mutation in *PTEN* (phosphatase and tensin homolog, deleted on chromosome 10) and characterized by the development of multiple hamartomas and carcinomas of the thyroid, breast, and uterus. Two thirds of Cowden syndrome patients develop thyroid tumors, including multinodular goiter, multiple adenomatous nodules, follicular adenoma, follicular carcinoma, and, less frequently, PTC.[61]

Follicular carcinoma is a major criterion and an important feature in *PTEN*-hamartoma tumor syndrome. These tumors are more frequently multicentric. PTC is rarely associated with this entity. Multiple adenomatous nodules in a background of lymphocytic thyroiditis and/or C-cell hyperplasia are distinctive findings in this syndrome. The Carney complex is a dominantly inherited syndrome characterized by spotty skin pigmentation, endocrine hormone overactivity, and myxomas. The presence of thyroid nodules is very common, but the risk of thyroid cancer is low (15%), and both PTC and FTC are present.[61] Werner syndrome is a rare autosomal recessive disease characterized by premature aging syndrome that typically begins in the third decade. Malignancy and cardiac disease are the most common causes of death in these patients. Patients have an approximately 3-fold increased risk for follicular carcinoma and six times increased risk for developing anaplastic thyroid carcinoma.[62]

Ionizing Radiation

A significant factor leading to thyroid cancer is ionizing radiation, particularly for papillary carcinoma, the most common thyroid cancer type. Both external radiation (x-ray and γ-radiation) and internal exposure to radioiodines through inhalation or ingestion carry an increased cancer risk.[63]

External radiation to the neck during childhood years increases the risk of PTC. The latency period between exposure and diagnosis is usually 5 years, and is maximal at approximately 20 years. A linear dose-response relationship is found between external irradiation and thyroid cancer, starting with radiation doses as low as 10 cGy and progressing up to 1500 cGy. A major risk factor is young age at the time of irradiation; after the age of 15 or 20 years, the risk is much reduced. In children exposed to a dose of 1 Gy (100 rad) to the thyroid, excess risk for thyroid cancer is 7.7-fold[64] (https://www.ncbi.nlm.nih.gov/pmc/articles/PMC2847020/).

Accidental exposure to γ-radiation and radioiodine as a result of nuclear weapon explosions or nuclear reactor accidents is another factor that increases the risk of thyroid cancer. The Chernobyl nuclear power accident in 1986 resulted in the development of cancer in more than 4000 individuals who were children or adolescents at the time of the accident.[65]

The dominant genetic alteration in radiation-induced tumors is chromosomal rearrangements, such as those leading to the formation of *RET/PTC, TRK,* and *BRAF/AKAP9* fusion oncogenes. Of note, *RET/PTC* rearrangements were found in up to 80% of radiation-induced papillary carcinomas.[66] This has been observed after accidental radiation exposure from Chernobyl, in patients treated by external beam radiation, and more recently in atomic bomb survivors in Japan. A very different mutation mechanism, i.e., point mutation, is the most prevalent in sporadic tumors, which typically carry point mutations in the *BRAF* and *RAS* genes.

Therapeutic administration of ^{131}I for hyperthyroidism (mean dose 506 MBq, mean follow-up of 15 years) was not associated with an increased incidence of thyroid cancer.[67] Kitahara and colleagues recently found that, in radioactive iodine therapy (RAI)-treated patients with hyperthyroidism, greater organ-absorbed doses appeared to be modestly positively associated with risk of death from solid cancer, including breast cancer.[68] It is postulated that the increased risk of cancer observed in this study may be related to the hyperthyroidism, and not necessarily the relatively low dose of RAI, although the two could be synergistic.

KEY POINTS

- Thyroid carcinoma is a genetically simple neoplasm with a low number of genetic alterations. It is one of the better characterized malignancies, where more than 90% of cases have a driver mutation or gene fusion identified.
- A comprehensive investigation of the genomic landscape of papillary thyroid carcinomas was reported by The Cancer Genome Atlas Network. These well-differentiated tumors were found to have a low frequency of somatic alterations, with the majority harboring mutually exclusive activating mutations in *BRAF* (60%) and *RAS*-family genes (13%).
- The most common oncogenic drivers in thyroid cancer include *BRAF* and *RAS* point mutations and *RET/PTC* and *PAX8/PPARγ* rearrangements. These nonoverlapping genetic alterations are found in more than 70% of papillary and follicular thyroid carcinomas. These molecular alterations can be of significant diagnostic, prognostic, and therapeutic utility.
- Progression of differentiated thyroid cancer to higher-grade cancer is associated with the accumulation of alterations in other genes, such as *TP53, PIK3CA, AKT1, CDKN2A/CDKN2B,* and the *TERT* promoter.
- Ionizing radiation can lead to thyroid cancer, primarily through chromosomal rearrangements.

DIAGNOSIS, CLINICAL FEATURES, AND COURSE

The most common presentation of thyroid cancer is as an incidental detection of small tumors, with widespread use of radiology studies of the head and neck. The observation that supports the subclinical disease detection hypothesis is the fact that the majority of the increase has been observed in small cancers, which cannot be palpated on exam even for most experienced clinicians. Small cancers are less likely to cause symptoms at the time of their discovery.[69]

Once the diagnosis of DTC is confirmed, the workup begins with a comprehensive history and physical examination. Neck pain, hoarseness, dysphagia, and dyspnea are rare symptoms, but these findings are suggestive of advanced thyroid cancer. Carcinoma should be suspected when the nodule is firm, when the nodule is not mobile with swallowing, when a nodule is found in children and adolescents, or if it is associated with ipsilateral enlarged lymph nodes. Rarely, distant metastases in the lung or the bone from thyroid cancer may be the initial symptom.

Measurement of thyroid-stimulating hormone (TSH) is necessary to rule out hyperfunctioning thyroid nodules, which are almost always benign nodules. Detection of thyroid autoantibodies suggests the presence of an underlying autoimmune disease. This is important to know preoperatively, as thyroglobulin (Tg) autoantibodies (TgAbs) have the potential to interfere with measurement of Tg protein, which is a valuable tumor marker for patients with DTC. Approximately 25% of DTC patients have TgAb detected in their circulation, as compared with 11% in the general population.[70]

Preoperative evaluation in patients with fine-needle aspiration revealing thyroid cancer is of extreme importance in planning initial treatment, which is mainly surgical. The ATA Guidelines published in 2015 strongly recommend preoperative neck ultrasound (US) for cervical (central and especially lateral neck compartments) lymph nodes for all patients undergoing thyroidectomy for malignant or suspicious for malignancy cytologic or molecular findings.[29] Patients with papillary cancer are expected to have clinically significant nodal disease in one third of cases. Computed tomography (CT) of the neck is particularly useful in identifying and delineating the full extent of any ETE or deep cervical lymphadenopathy. Neck CT should be considered for patients with significant adenopathy, or clinical signs or symptoms of more advanced disease (very large primary tumor, dysphagia, or hoarseness). The best CT assessment is achieved with the administration of intravenous contrast.[71] The use of contrast would delay the treatment with postoperative radioactive iodine for up to 6 to 8 weeks. This is usually the amount of time between the standard preoperative evaluation, thyroid surgery, and follow-up evaluation to determine if radioiodine therapy, adjuvant therapy, or remnant ablation is indicated. Contrast-enhanced CT is particularly helpful in nodal disease in the parapharyngeal, retrolaryngeal, retrotracheal, and retrosternal regions. This radiographic combination of US and contrast CT produces an effective preoperative nodal map that enables surgeons to direct the nodal dissection at the time of surgery.[71] Magnetic resonance imaging (MRI) can also be used to evaluate the thyroid gland and surrounding soft tissues of the neck with great resolution, although the cost of MRI is higher than that of CT.

Vocal cord paralysis or paresis may be present without significant vocal symptoms in patients with DTC. Subtle voice changes are sometimes not recognized by patients and could be difficult for clinicians to detect. Conversely, recurrent laryngeal nerve injury is one the most common causes of postoperative voice changes, and it occurs more often in surgeons who perform a low number of thyroid surgeries per year.[72] All these reasons provide a rationale for the inclusion of vocal cord examination in many or most patients. A recent American Head and Neck Society (AHNS) consensus statement recommended preoperative laryngoscopy in all patients with thyroid malignancy,[73] although the ATA guidelines recommended more selective use of the laryngeal exam for patients with preoperative voice abnormalities, history of previous cervical or upper chest surgery, or known thyroid cancer with posterior ETE or extensive cervical metastases.[29] The AHNS has concluded that flexible transnasal laryngoscopy is the optimal laryngeal examination technique.[73]

Papillary carcinomas represent the largest group of well-differentiated thyroid carcinomas with several histologic variants. Papillary carcinomas occur at any age, with highest frequency in the fourth or fifth decades of life. Clinically apparent cervical lymph node metastases are found in 12% to 14% of patients; approximately 10% have extrathyroidal invasion, and 3% to 6% have distant metastases. The most common site of ETE is the surrounding muscle (8%), recurrent laryngeal nerve (6%), and trachea (5%).[72] PTC has good prognosis in most patients and rarely causes death in patients younger than 55 years. Positive cervical nodes do not seem to carry an adverse risk in young individuals, but they do carry a higher risk of recurrence. Small-volume subclinical microscopic nodal disease conveys a much smaller risk of recurrence than large-volume, macroscopic clinically apparent locoregional metastases. The number of positive nodes and the presence of extranodal extension (median risk of recurrence 24%) are also associated with higher risk of recurrence.[74] The most common site of distant metastases is the lungs.[37,75] Pulmonary metastases most commonly present as micronodules (<1 cm), initially located at the lung bases. Children experience lymph node or pulmonary metastases more often than do adults, but mortality from thyroid cancer is extremely low in children.[76] Distant metastases occur in 1% to 25% of PTC patients, representing the lowest rate of all the well-differentiated thyroid carcinomas.[77] The American Cancer Society (ACS) estimates the overall 5-year survival for patients with PTC at greater than 99%, 99% for those with regional neck metastases, and 78% for those with distant metastases.[78]

Follicular thyroid cancers are the second most prevalent type, and they account for 10% to 15% of all thyroid cancers. They occur at an older age, with peak incidence in the fifth decade of life. They commonly present as a slowly growing thyroid mass, with direct invasion of the strap muscles and trachea occurring in up to 25% of patients. They involve cervical lymph nodes in 5% to 10% of cases, although many of these may be FVPTC. FTC has a higher rate of hematogenous spread than PTC and can present with distant metastases in 10% to 20% of patients. The most common sites of distant metastases are lungs and bone. FTC is a slightly more aggressive well-differentiated thyroid cancer than PTC. The ACS estimates 5-year survival at 98% overall, and 96% and 63% for those with locoregional disease and distant metastatic FTC, respectively.[78]

In a study from Shaha et al., adverse prognostic factors included age older than 45 years, Hurthle cell subtype, ETE, tumor size exceeding 4 cm, or the presence of distant metastasis.[79]

HCCs used to be considered a subtype of FTC, but they are now considered a separate entity, given their unique biological and clinical features and different genetic profile than FTC.[57] These tumors have a higher rate of lymph node metastases than FTC. They also have the highest incidence of distant metastases of all the well-differentiated thyroid carcinomas. In a cohort of 988 patients with well-differentiated thyroid cancer, 34% of patients with HCC had distant metastases.[80]

KEY POINTS

- The most common presentation of thyroid cancer is as an incidental detection of small thyroid cancers, with widespread use of radiology studies of the head and neck.
- Preoperative evaluation in patients with fine-needle aspiration is very important for planning initial treatment, which is primarily surgical.
- Vocal cord paralysis or paresis may be present without significant vocal symptoms in patients with differentiated thyroid carcinoma.
- Positive cervical nodes do not seem to carry an adverse risk in young individuals, but they do carry a higher risk of recurrence.
- Hurthle cell carcinomas are now considered a separate entity, given their unique biological and clinical features and different genetic profile than follicular thyroid carcinoma. These tumors have the highest incidence of distant metastases of all the well-differentiated thyroid carcinomas.

STAGING, RISK OF RECURRENCE, AND RESPONSE TO THERAPY

The staging system most often used for thyroid cancer is the American Joint Committee on Cancer (AJCC) TNM system, which is based on three key pieces of information: T (tumor) for extent (size and ETE) of the tumor, N (lymph nodes) for cervical lymph node involvement, and M for distant metastases.[81] This system is designed to predict survival in patients with cancer (see https://www.facs.org/quality-programs/cancer/ajcc for AJCC classification). Most of the changes in the eighth edition of AJCC staging (effective January 2018) were made to downstage a significant number of patients into lower stages that more accurately reflect their low risk of dying from thyroid cancer.

The main changes consisted in raising the age cutoff from 45 to 55 years of age at diagnosis. This change downstaged a large number of patients into stage I, without significantly altering the mortality associated with various stages. It is increasingly recognized that mortality increases progressively with advancing age and is considered as a continuous variable, beginning at approximately 35 years of age.[82]

The other main changes were removing microscopic ETE from the definition of T3 disease and moving regional lymph node metastases from stage III to stage II in older patients. The eighth edition also reemphasizes the critical importance of gross ETE as an unfavorable prognostic factor, while minimizing the significance of minor extension through the thyroid capsule, which is identified only on histological examination.[82] All data for the staging of a tumor should be accumulated preoperatively, intraoperatively, and during the early follow-up period after thyroid surgery. This would impact the initial therapeutic decision-making and the follow-up management strategies.

Over the past few years, the approach to patients with DTC has been changing from intense initial treatment (surgery, radioactive iodine treatment, TSH suppressive therapy) to less intensive management for lower-risk disease.

Recognizing that the commonly used clinicopathologic staging systems were designed to predict death and not recurrence, the 2009 ATA guidelines proposed the first risk stratification system to predict risk of recurrent/persistent disease in DTC, which was updated in 2015.[29,83] The risk of recurrence was divided into three categories (low, intermediate, and high), based on tumor-related parameters (TNM and histologic variant) integrated with other clinical features (the first post-therapy radioiodine whole-body scan and serum Tg measurement). Low-risk patients were defined as having intrathyroidal DTC with no evidence of ETE, vascular invasion, or metastases. Intermediate-risk patients demonstrated microscopic ETE, cervical lymph node metastases, RAI-avid disease in the neck outside the thyroid bed, vascular invasion, or aggressive tumor histology. High-risk patients had gross ETE, incomplete tumor resection, distant metastases, or inappropriate postoperative serum Tg values (Table 78.3).

In 2015, the ATA guidelines incorporated additional prognostic variables (such as the extent of lymph node involvement, mutational status, and/or the degree of vascular invasion in FTC) not included in the 2009 ATA initial risk stratification system.[29] This updated risk stratification scheme for thyroid cancer increased the number of low-risk thyroid cancer, mainly due to low-volume lymph nodal metastases being considered low risk. The other key 2015 ATA changes included that lobectomy could be considered as the initial surgical approach for follicular cell-derived thyroid cancers from 1 to 4 cm in size and surveillance following primary treatment of small PTC. In summary, the 2015 ATA guidelines emphasized the more individualized, and often less aggressive, management of thyroid nodules and DTC.

TABLE 78.3 Initial American Thyroid Association Risk of Recurrence Classification (2009 Guidelines)

Low Risk	Intermediate Risk	High Risk
All the following are present	*Any of the following is present*	*Any of the following is present*
No local or distant metastases	Microscopic invasion into the perithyroidal soft tissues	Macroscopic tumor invasion
All macroscopic tumor has been resected	Cervical lymph node metastases or ^{131}I uptake outside the thyroid bed on the post-treatment scan done after thyroid remnant ablation	Incomplete tumor resection with gross residual disease
No invasion of locoregional tissues	Tumor with aggressive histology or vascular invasion (e.g., tall cell, insular, columnar cell carcinoma, Hurthle cell carcinoma, follicular thyroid cancer)	Distant metastases
Tumor does not have aggressive histology (e.g., tall cell, insular, columnar cell carcinoma, Hurthle cell carcinoma, follicular thyroid cancer)		
No vascular invasion		
No ^{131}I uptake outside the thyroid bed on the posttreatment scan, if done

Erratum in: Thyroid. 2010;20:674–675.

Response to Therapy

While these initial staging systems provide an important starting point for risk assessment, they are static representations of the patient at the time of initial therapy and are not designed to be modified over time based on the clinical course of the disease. In 2010, Tuttle et al. developed a new concept of "ongoing risk stratification," which better defines the patient risk based on the results of the initial treatment.[84] These concepts integrate the initial risk stratification (at the time of diagnosis) with the clinical, radiologic, and laboratory data becoming available during follow-up. In this study, which consisted of a retrospective review of 588 consecutive thyroid cancer patients followed for a median of 7 years at a single tertiary-care referral center, the ATA risk stratification system for prediction of early recurrence of disease was validated, and it was demonstrated how these initial risk estimates can be refined by incorporating response to therapy variables. The effect of therapy was integrated into the risk assessments, in which clinical data obtained during the first 2 years of follow-up were used to categorize response to therapy as excellent, acceptable, or incomplete.[84]

When patients were restratified at 6 to 12 months after initial treatment, a significant number of patients who were initially considered high-risk were reclassified as low-risk, and a large number of these patients continued to be in apparent remission up to the end of follow-up. The ongoing risk stratification allowed better modulation of the subsequent follow-up, excluding significant number of intermediate-/high-risk patients from unnecessary workup or treatment. Furthermore, the initial ATA risk estimates can be significantly refined based on the assessment of response to initial therapy, providing a dynamic risk assessment that can be used effectively for ongoing follow-up recommendations.

In 2011, the same group further subdivided the group of incomplete response to therapy into either biochemical (Tg elevations in the absence of structurally identifiable disease to widespread) or structural evidence of disease (widespread, progressive structural disease). This subdivision of the incomplete response to therapy category more precisely predicted clinical outcomes. A structural incomplete response to initial therapy was associated with significantly worse clinical outcome than a biochemical incomplete response to therapy.[85] This response to therapy classification was endorsed by the 2015 ATA guidelines, given that the risk of recurrence and disease-specific mortality can change over time as a function of the clinical course of the disease and the response to therapy.[29]

The response to therapy assessment was initially validated for dynamic risk stratification in patients with DTC treated with total thyroidectomy (TT) and RAI. A subsequent study was conducted to validate the response to therapy assessment in patients with DCT treated only with lobectomy or TT without RAI. The study demonstrated that the 2015 ATA risk stratification system effectively defined short-term risk of having recurrent/persistent disease in patients with DTC treated with total lobectomy alone or TT without RAI.[86]

Table 78. 4 summarizes the initial risk stratification of thyroid cancer, which requires the information obtained from the histologic description of the primary tumor and metastatic foci removed at the time of initial surgery and other important preoperative and intraoperative findings.[87]

KEY POINTS

- Most of the changes in the eight edition of American Joint Committee on Cancer staging were made to downstage a significant number of patients into lower stages that more accurately reflect their low risk of dying from thyroid cancer.
- Recognizing that the commonly used clinicopathologic staging systems were designed to predict death and not recurrence, the 2009 American Thyroid Association guidelines proposed the first risk stratification system to predict risk of recurrent/persistent disease in differentiated thyroid cancer, which was updated in 2015.
- The concept of "ongoing risk stratification" integrates the initial risk stratification (at the time of diagnosis) with the clinical, radiologic, and laboratory data becoming available during follow-up. This allowed better modulation of the subsequent monitoring because the risk of recurrence and disease-specific mortality can change over time as a function of the clinical course of the disease and the response to therapy.

TABLE 78.4 Response to Therapy Definition Based on Initial Therapy

	Total Thyroidectomy and RAI Ablation	Total Thyroidectomy without RAI Ablation	Lobectomy
Excellent response	Nonstimulated Tg level <0.2 ng/mL or Stimulated Tg level <1 ng/mL and Undetectable TgAb and Negative imaging	Nonstimulated Tg level <0.2 ng/mL or Stimulated Tg level <1 ng/mL and Undetectable TgAb And Negative imaging	Stable, nonstimulated Tg level <30 ng/mL and Undetectable TgAb and Negative imaging
Biochemical incomplete Response	Nonstimulated Tg level >1 ng/mL or Stimulated Tg level >10 ng mL and Increasing TgAb and negative imaging	Nonstimulated Tg level >5 ng/mL or Stimulated Tg level >10 ng mL and Increasing Tg values over time with similar TSH levels or Increasing TgAb levels and Negative imaging	Nonstimulated Tg level >30 ng/mL or Increasing Tg values over time with similar TSH levels or Increasing TgAb levels and Negative imaging
Structural incomplete response	Structural or functional evidence of disease regardless Tg or TgAb	Structural or functional evidence of disease regardless of Tg or TgAb	Structural or functional evidence of disease regardless of Tg or TgAb
Indeterminate response	Nonspecific findings on imaging studies or Faint uptake in thyroid bed on RAI scanning or Nonstimulated Tg level 0.2–1 ng/mL or Stimulated Tg level 1–10 ng/mL or TgAb levels stable or declining in the absence of structural or functional disease	Nonspecific findings on imaging studies or Faint uptake in thyroid bed on RAI scanning or Nonstimulated Tg level 0.2–5 ng/mL or Stimulated Tg level 2–10 ng/mL or TgAb levels stable or declining in the absence of structural or functional disease	Nonspecific findings on imaging studies or TgAb levels stable or declining in the absence of structural or functional disease

PROGNOSTIC FACTORS

Most patients with DTC have high cure rates after initial treatment, but a significant minority are at risk for recurrent disease, and a much smaller minority are at risk for cancer-related death.

Age and Gender

Age and gender are two important prognostic factors to be considered in the evaluation of thyroid cancer patients. In children and adolescents, despite a high risk of metastases and recurrent disease (up to 40%), there is an excellent prognosis, which is greater than 98% at 10 years. A study by Elisei et al., where over 4000 patients with thyroid carcinoma were studied, concluded that male gender and older age presented a significant negative influence on survival rate at univariate analysis, but in multivariate analysis, only an age older than 60 years was an independent poor prognostic factor.[88] Jonklaas et al. examined gender differences and found that women experienced a better prognosis only in univariate analysis. When the analysis also included age and disease stage, both genders had the same prognosis. The same trend was confirmed when analysis was performed distinguishing between age at diagnosis. Women diagnosed before 55 years old showed a better prognosis than men. There were no differences between sexes after age 55 years.[89] Older patients tend to have more locally aggressive tumors, a higher incidence of distant metastases at diagnosis, and more aggressive histologic variants.

Histopathological Factors

TCVPTC is considered a more aggressive variant of PTC, with a poor prognosis. This is largely due to the tendency for TCVPTC to present at an older age and with ETE, but even when the major prognostic factors for thyroid cancer are controlled for, including age and ETE, tall-cell histology alone remains a significant prognostic factor for disease-specific death.[90]

DSVPTC also exhibits aggressive biological behavior. A recent metanalysis that included 585 DSVPTC and 64,611 classical PTC patients found that, relative to patients with classical PTC, patients with DSVPTC exhibited a higher risk of ETE and lymph node and distant metastases. The risk of persistent/recurrent disease was three times higher in patients with DSVPTC than it was in classical PTC patients. The risk of cancer-related mortality was not different between DSVPTC and classical PTC.[91]

A good prognosis is generally found with the encapsulated and follicular variants of PTC.[92]

Widely invasive follicular cancers present a less favorable prognosis than minimally invasive tumors do. A recent population-based study found that the 5-year and 10-year cancer-specific survival rates for Hurthle cell carcinomas were 95.4% and 92.6%, respectively.[93] Male gender, multifocal tumors, and extended tumors were associated with increased risk of late-stage HCC. Age over 45 years, distant SEER stage, and late T-stage were independent risk factors for mortality in HCC.[93]

Size of the Primary Tumor and Extrathyroidal Extension

Papillary thyroid microcarcinoma, defined as a tumor with a larger diameter less than or equal to 1 cm, is considered to have an indolent course and an excellent prognosis, whatever the extent of the primary surgical treatment. The 2015 ATA guidelines included this entity in the low-risk category, not recommending postoperative RAI. These guidelines also recommended active surveillance management as an alternative to surgery in patients without evidence of lymph node metastasis or local invasion.[29] Several series have reported a progressive increase in risk for recurrence and tumor-specific mortality with increasing size of the primary tumor.

Extrathyroidal Extension

ETE is present in 5% to 10% of papillary tumors (approximately 10% have minimal ETE, and 4% to 5% have extensive ETE) and in 3% to 5% of follicular tumors; it exposes the patient to higher rates of local recurrence and distant metastases, as well as to a higher percentage of tumor-related death. Sosa and colleagues[94] studied more than 240,000 patients with DTC and evidence of ETE. After adjustment, minimal ETE (HR 1.13; $P < 0.01$) and extensive ETE (HR 1.74; $P < 0.01$) were associated with compromised survival for patients with DTC.

Lymph Node Metastases

Lymph node metastases are present in 10% to 80% in different series of papillary carcinoma and much less often (nearly 5% to 10%) in the follicular carcinoma. Local node involvement could be found in large tumors as well as in microcarcinomas. A study of the SEER database of 9904 patients with PTC found that the survival of patients with well-differentiated thyroid cancer is adversely affected by lymph node metastases, with an overall survival at 14 years of 82% for node-negative and 79% for node-positive patients ($P < 0.05$).[95] A more recent analysis of the National Cancer Database and SEER showed a small but significantly increased risk of death for patients younger than 45 years with lymph node metastases compared with younger patients without involved lymph nodes, and that increasing number of metastatic lymph nodes up to six involved nodes confers additional mortality risk in this age group.[96] Characteristics of the lymph node metastases can further discriminate the risk of recurrence to the patient, especially in those with small-volume microscopic disease, which conveys a much lower risk of recurrence than clinically evident locoregional metastasis, multiple, larger, and/or extracapsular nodal extension.[97]

KEY POINTS

- Age is an important prognostic factor in the evaluation of thyroid cancer patients. In children and adolescents, despite a high risk of metastases and recurrent disease, there is an excellent prognosis. Older patients tend to have more locally aggressive tumors, a higher incidence of distant metastases at diagnosis and more aggressive histologic variants. Papillary thyroid microcarcinoma is considered to have an indolent course and an excellent prognosis, whatever the extent of the primary surgical treatment. There is a progressive increase in risk for recurrence and tumor-specific mortality with increasing size of the primary tumor.
- The tall-cell variant of papillary thyroid carcinoma (PTC) is considered a more aggressive variant of PTC, with a poor prognosis.
- Lymph node metastases are present in 10% to 80% of patients with PTC. Characteristics of the lymph node metastases can further discriminate the risk of recurrence to the patient, with greater risk of recurrence when there are clinically evident locoregional metastasis, multiple, larger, and/or with extracapsular nodal extension.

THERAPY AND MONITORING

The primary goal of DTC treatment and monitoring is to ensure the most effective and least invasive treatment and monitoring plan for a disease that is often cured with surgery alone, or even active surveillance for some patients, and is rarely fatal. The 2015 ATA guidelines have summarized the basic goals of initial therapy for patients with DTC in: 1) improving the overall and disease-specific survival, 2) reducing the risk of persistent/recurrent disease and associated morbidity, and 3) permitting accurate disease staging and risk stratification, while minimizing treatment-related morbidity and unnecessary therapy.[29]

The most important initial treatment in tumors greater than 1 cm is the surgical removal of the primary tumor, disease that has extended beyond the thyroid capsule, and clinically significant lymph node metastases. Preoperative evaluation and eventual completeness of surgical resection is an important determinant of outcome, because residual metastatic lymph nodes represent the most common site of disease persistence/recurrence.[97]

When considering the extent of surgery in a patient with biopsy-proven thyroid cancer, several high-risk features (clinical N1 disease, gross ETE, recurrent laryngeal nerve involvement) should be considered. Previous guidelines have endorsed TT as the primary initial surgical treatment option for nearly all DTCs greater than 1 cm with or without evidence of locoregional or distant metastases, based on studies that suggested that TT would improve survival and decrease recurrence rates and would facilitate follow-up in low- to intermediate-risk patients by receiving RAI ablation.[83] More recent studies hat have demonstrated that, in properly selected lower-risk patients (tumor diameter ≤40 mm, no clinical lymph node metastasis or extrathyroidal invasion), clinical outcomes are very similar following unilateral or bilateral thyroid surgery.[98-103] Furthermore, the current, more selective, approach to RAI ablation in low- to intermediate-risk patients would not necessarily indicate the need for bilateral surgery in many of those patients.

The 2015 ATA guidelines recommend a near-total thyroidectomy or TT and gross removal of all primary tumor for patients with thyroid cancer greater than 4 cm, or with gross ETE (clinical T4), or clinically apparent metastatic disease to nodes (clinical N1) or distant sites (clinical M1). For patients with thyroid cancer greater than 1 cm and less than 4 cm without ETE, and without clinical evidence of any lymph node metastases (cN0), the initial surgical procedure can be either a bilateral procedure (near total thyroidectomy or TT) or a unilateral procedure (lobectomy). Thyroid lobectomy alone is likely sufficient initial treatment for low-risk papillary and follicular carcinomas. In many low-risk patients, the presence of the remaining lobe of the gland may obviate the lifelong need for exogenous thyroid hormone therapy. It is also important to note that even high-volume surgeons (>100 cases/year) have a higher overall postoperative complication rate when performing TT compared with lobectomy.[98]

If surgery is chosen for patients with thyroid cancer less than 1 cm without ETE and cN0, the initial surgical procedure should be a thyroid lobectomy, unless there are clear indications to remove the contralateral lobe (absence of prior head and neck radiation, familial thyroid carcinoma).[29]

There is no evidence that prophylactic central node dissection, without clinical evidence of nodal disease, improves recurrence or mortality rate. Microscopic nodal disease does not carry the recurrence risk of macroscopic clinically detectable disease.[97] The 2015 ATA guidelines recommend considering prophylactic central neck dissection only when patients have evidence of advanced primary tumors (T4) or clinically involved lateral neck nodes (cN1b), or if the information will be used to plan further steps in therapy.[29] Thyroidectomy or lobectomy without prophylactic central neck dissection is appropriate for small (T1 or T2), noninvasive, clinically node-negative PTC (cN0) and for most follicular cancers. TT should be accompanied by therapeutic central-compartment (level VI) neck dissection in patients with clinically involved central nodes, and therapeutic lateral neck compartmental lymph node dissection should be performed for patients with biopsy-proven metastatic lateral cervical lymphadenopathy.[29]

Radioiodine Therapy

When one considers the use of radioiodine after surgery for DTC, it is helpful to consider three basic categories of treatment: 1) therapy—the use of radioiodine to treat known residual or metastatic disease with the intent of improving survival and/or disease progression, 2) adjuvant therapy—treating a patient who will be undergoing surgery with curative intent who is at higher risk for recurrence, with the intent of lowering that risk of recurrence, and 3) remnant ablation—the intent of ablating residual normal thyroid tissue to improve the ability for disease monitoring. For the majority of DTC patients, the effect of RAI on decreasing locoregional recurrence and improving disease-specific and overall survival remains unclear. There are no reported prospective, randomized trials that evaluate the outcome of RAI in different recurrence risk categories, although there are currently two ongoing trials in lower-risk patients (IoN [NCT01398085] and ESTIMABL2 [NCT01837745]). In the last several years, increased emphasis has been placed on using individual estimates of risk to guide radioiodine use and follow-up in DTC patients. Recurrence risk stratification is a good starting point for initial decision-making.[84] Several studies have shown significant improvement in overall and disease-specific mortality, as well as disease-free survival, in stage III and IV patients; therefore, radioiodine adjuvant therapy is indicated in most high-risk patients. In a majority of low-risk patients, radioiodine ablation it is not recommended, as it is unclear if its administration has any significant benefit after complete surgical resection. Most patients can be easily monitored for disease recurrence with neck US and serum Tg, even if remnant ablation has not been used. In patients at intermediate risk, radioiodine adjuvant therapy may be considered, but the decision must be individualized.[29]

Effective treatment with radioiodine requires adequate stimulation by TSH. This may be achieved by thyroid hormone withdrawal (THW) or after recombinant human TSH (rhTSH) administration. The latter procedure is often the method of choice based on several reports demonstrating comparable efficacy compared with THW and better patient acceptance.[99] Guidelines also recommend a low iodine diet for approximately 1 to 2 weeks before RAI treatment.[29]

There is no consensus regarding the optimal administered activity RAI. Postoperative dosing regimens vary from low “ablation” doses (1.1 GBq or 30 mCi) to high “treatment” (5.5 GBq or 150 mCi) doses. The publication of two large randomized controlled trials (ESTIMABL1 and HiLo) of low-risk patients, in which the rate of successful remnant ablation was the same with either 1.1 GBq or 3.7 GBq dose activities of ^{131}I, and with either THW or with the use of rhTSH, suggested that low doses after preparation with rhTSH are a reasonable approach for remnant ablation when used in low- to intermediate-risk patients.[104,105] When considering adjuvant therapy in intermediate- to higher-risk patients, limited database studies suggest that 50 to 150 mCi ^{131}I should be considered based on individual patient and tumor characteristics.

Levothyroxine Therapy

Immediately after surgery, thyroid hormone therapy is initiated with two aims: to replace thyroid hormone and to suppress the potential growth stimulus of TSH on tumor cells (TSH suppressive therapy) in a subset of patients with higher-risk disease. Retrospective and prospective studies have demonstrated that TSH suppressive treatment to below 0.1 mU/L may improve outcomes in high-risk thyroid cancer patients reducing thyroid cancer mortality,[106,107] though no such evidence of benefit has been documented in low-risk patients. The results of these studies suggest that more aggressive TSH suppression with levothyroxine (LT4) is important in patients with high-risk disease or recurrent tumor, whereas less aggressive TSH suppression, or no suppression at all, is reasonable in low-risk patients. There are no studies that specifically examine intermediate-risk patients, because many of the older studies did not apply risk-of-recurrence stratification.

The 2015 ATA guidelines recommend TSH suppression to below 0.1 mU/L for high-risk thyroid cancer patients, TSH suppression to 0.1 to 0.5 mU/L for intermediate-risk patients, and TSH to be maintained at the lower end of the reference range (0.5– 2 mU/L) in low-risk patients. For low-risk patients who have undergone lobectomy, TSH may be maintained in the mid to lower reference range (0.5–2 mU/L). Thyroid hormone therapy may not be needed if patients can maintain their serum TSH in this target range.[29]

Monitoring for Disease Recurrence

The majority of recurrences are detected in the first 5 years after diagnosis. Late recurrences occur in a minority of cases, even 20 years after the initial treatment; however, with the use of high-resolution neck US and sensitive Tg assays for monitoring, these late recurrences are becoming less frequent. During initial follow-up, a 6- to 12-month physical examination, neck US, basal serum Tg measurement, and mandatory TgAb measurement are the most useful tools to monitor for the presence of persistent or recurrent disease. Serum Tg and TgAbs ideally should be measured using the same assay for each patient. Newer methods for serum Tg measurement with functional sensitivity at or below 0.1 ng/mL are currently available, which have replaced the need for Tg stimulation by THW or rhTSH, because stimulation does not provide additional useful information in most patients.[108]

Subsequent follow-up of patients who are considered to have no evidence of disease (excellent response) at the time of their first follow-up should consist of physical examination, basal serum Tg measurement on LT4 therapy, and neck US. Over time, the cancer-monitoring interval may be increased from yearly to every 5 years as long as the patient continues to have an excellent response to therapy.

Cervical US is highly sensitive in the detection of cervical metastases in patients with DTC. US is an operator-dependent procedure that should be performed by those with experience in identifying normal and abnormal neck lymph nodes. Following surgery, the 2015 ATA guidelines recommend that a cervical US to evaluate the thyroid bed and central and lateral cervical nodal compartments should be performed at 6 to 12 months and then periodically, depending on the patient's risk for recurrent disease and response to therapy. If a positive result would change management, ultrasonographically suspicious lymph nodes of 8 to 10 mm in the smallest diameter should be biopsied for cytology, with Tg measurement in the needle washout fluid. Suspicious lymph nodes less than 8 to 10 mm in the smallest diameter may be followed without biopsy, with consideration for fine-needle aspiration or intervention if there is growth or if the node threatens vital structures, generally in the central neck.[29] Diagnostic whole-body scan (WBS), either following THW or rhTSH, 6 to 12 months after adjuvant RAI therapy can be useful in the follow-up of patients with high or intermediate risk (higher-risk features) of persistent disease. Single-photon emission CT/CT RAI imaging is preferred over planar imaging in patients with uptake on planar imaging to better anatomically localize the RAI uptake and distinguish between likely tumors and nonspecific uptake.[29]

(^{18}F)-fluorodeoxyglucose–positron emission tomography (FDG-PET) scanning should be considered in the evaluation of high-risk DTC patients with elevated serum Tg (generally >10–20 ng/mL on LT4 therapy) with negative RAI imaging, as diagnostic of metastatic disease and also as a prognostic tool. Patients with a negative ^{131}I-WBS and positive FDG-PET have a more aggressive and less differentiated disease, with worse prognosis.[109]

CT scan of chest without intravenous (IV) contrast (imaging pulmonary parenchyma) or with IV contrast (to include the mediastinum) should be considered in high-risk DTC patients with elevated serum Tg (generally >10 ng/ mL) or rising TgAbs. Imaging of other organs including MRI brain, magnetic resonance skeletal survey, and/or CT or MRI of the abdomen should be considered in high-risk DTC patients with elevated serum Tg (generally >10 ng/mL) and negative neck and chest imaging.[29]

In Table 78.5, we summarize the use of ongoing risk stratification, modified from 2015 ATA guidelines.[29]

TABLE 78.5 Ongoing Risk Stratification—Modified from 2015 American Thyroid Association Guidelines

	Excellent	Indeterminate	Biochemical Incomplete	Structural Incomplete
TSH target	0.5–2	0.1–0.5	<0.1	<0.1
Serum Tg	Yearly	Yearly	6–12 months	3–6 months
Neck US	5 years	1–3 years	6–12 months	3–6 months
Stim Tg	No	Maybe	Consider	Consider
WBS	No	Maybe	Consider	Consider
Cross-sectional imaging	No	No	Consider	Yes

TSH, Thyroid-stimulating hormone; *Tg*, thyroglobulin; *US*, ultrasound; *WBS*, whole-body scan.

Treatment of Metastatic Disease

Distant Metastases. Distant metastases are observed in approximately 10% of DTC patients, and half of them are detected at presentation. They are usually located in the lungs (50%), bones (25%), or lungs and bones (20%), or at other sites (5%). Distant metastases at diagnosis confer an increase in morbidity and mortality in patients with PTC or FTC, but individual prognosis depends on several factors. In a study of patients with lung metastases from DTC who were observed for 40 years, young age at diagnosis and ^{131}I uptake by metastases were the most important factors positively affecting survival time. RAI could also lead to longer survival time or complete recovery.[110] Another retrospective study showed that age of 45 years or more, symptoms, site other than lung only or bone only, and no RAI for the metastasis were predictors of poor outcome, with 13%, 11%, 16%, and 12% 10-year disease-specific survival, respectively.[112] Improved survival in patients with distant metastases is also associated with responsiveness to directed therapy (external beam radiation therapy, thermal ablation, surgery, etc.) and/or RAI.[113]

Surgery. After primary surgery, recurrences in the neck may develop in the thyroid bed and in surrounding soft tissues or in the regional lymph nodes. Any clinically detectable local biopsy-proven persistent or recurrent disease should be treated by surgery if possible, although reoperations involving central neck dissection are difficult and increase the risk of complications to the parathyroid glands and recurrent laryngeal nerve. Recurrent disease in the lateral cervical nodes is easier to treat surgically, because the operative field has not been dissected previously. The preferred surgical procedure is a modified radical neck dissection.[114] Most studies suggest that surgery results in a high clearance rate of structural disease in over 80% of patients.

Lung metastases that do not concentrate radioactive iodine could be treated surgically in very selected cases, such as a single macronodular lesion or more than one in the same lobe. Bone metastasis surgery is generally palliative, as required in pathologic fractures or to ameliorate neurologic symptoms resulting from spinal cord compression by vertebral metastases.

Radioactive Iodine. RAI could be used for regional nodal metastases discovered on diagnostic WBS, and could be employed in patients with low-volume disease or in combination with surgery. Significant variation exists in regard to RAI use, irrespective of the degree of disease or risk of recurrence.

Micronodular diffuse lung metastases shown by WBS in the absence of radiographic changes have the greatest chance of remission when treated with RAI.[115] This is important in children, who often have a diffuse pattern of metastatic pulmonary spread and do exceptionally well with RAI. Adult patients should be treated with RAI repeatedly every 6 to 12 months as long as disease continues to concentrate RAI and respond clinically; a cumulative administered activity of 600 mCi ^{131}I is a limit in many patients. Children should be treated at longer intervals, 24 to 36 months if possible, and lower cumulative administered activities. In adult patients, the treatment dose is usually 100 to 200 mCi (or 100–150 mCi for patients ≥70 years old). Lower doses (approximately 1 mCi/kg body weight) should be used in children with lung metastases, particularly of the diffuse type, to avoid the risk for radiation-induced pulmonary fibrosis.[116]

Radioiodine-avid lung macronodules may benefit from RAI, but the ability to achieve and excellent response is very low.

RAI of iodine-avid bone metastases has been associated with improved survival and should be employed, although RAI is rarely curative.[117] The treatment dose can be given empirically (100–200 mCi) or determined by dosimetry.

Radioactive-iodine refractory thyroid cancer is defined in four ways: (i) the malignant metastatic tissue does not ever concentrate RAI (no uptake outside the thyroid bed at the first therapeutic WBS), (ii) the tumor tissue loses the ability to concentrate RAI after previous evidence of RAI-avid disease (in the absence of stable iodine contamination), (iii) RAI is concentrated in some lesions but not in others; and (iv) metastatic disease progresses despite significant concentration of RAI.[118] When a patient with DTC is classified as refractory to RAI, there is generally no indication for further RAI treatment.

Directed Therapy. Several local treatment modalities to induce tumor control, other than surgery, may be used to treat distant metastatic disease in the brain, lung, liver, and bone lesions from thyroid carcinoma. The most commonly used techniques include surgery, thermal ablation (radiofrequency ablation or cryotherapy), stereotactic body radiation therapy, or intensity-modulated radiotherapy. The main principle of these techniques is to selectively treat the lesion, especially when patients are symptomatic or at risk for complications, be minimally invasive, and be well tolerated with few side effects.

Systemic Therapy. In 80% of PTCs, constitutive activation of the MAPK signaling pathway is the initiating event in the carcinogenesis of PTC. This includes *RET/PTC* rearrangement and point mutations in *RAS* and *BRAF*, with no overlap between these mutations in primary tumors. The PI3K pathway may also be activated in a few papillary and follicular cancers. Acquisition of additional mutations and gene amplifications that activate this pathway may be a common event in PDTCs. Angiogenesis is another potential molecular target for therapy. Various vascular endothelial growth factors (VEGF) and VEGF receptors (VEGFR-1 [FLT1] and VEGFR-2 [KDR]), as well as receptors for the fibroblast growth factor and for the platelet-derived growth factor, are often overexpressed in the vascular endothelium of thyroid cancer tissues, and they also trigger the MAPK signaling pathway.

Molecules that block kinase activity at distal steps in the MAPK pathway have been identified as drugs for refractory thyroid cancer. These tyrosine kinase inhibitors are multikinase inhibitors that share the ability to inhibit VEGF receptor and other receptor tyrosine kinases. Kinase inhibitor therapy should be considered in RAI-refractory DTC patients with metastatic, rapidly progressive, symptomatic, and/or imminently threatening disease not otherwise amenable to local control using other approaches.[29] Benefit has been demonstrated in the form of improved progression-free survival (delay in time to disease progression or death) in three randomized, double-blinded, placebo-controlled clinical trials of vandetanib,[119] sorafenib,[120] and lenvatinib.[121] On this basis, sorafenib and lenvatinib were approved for use in the United States and the European Union for patients with advanced RAI-refractory DTC. To date, no clinical trial has demonstrated an overall survival advantage or improved quality of life from use of any therapy in RAI-refractory DTC.[120,121]

Advances in understanding the genomic and functional alterations contributing to the pathogenesis of thyroid cancers have opened new therapeutic opportunities and are beginning to improve patient outcomes. In addition to the multiple kinase inhibitor drug approvals for each subtype of thyroid cancer, there are several US Food and Drug Administration indications that are mutation-specific: dabrafenib/trametinib for *BRAF*-mutated anaplastic thyroid cancer, larotrectinib and entrectinib for *NTRK*-fusion thyroid cancer, and selpercatinib and pralsetinib for *RET*-mutated thyroid cancer. Furthermore, other mutation-specific drugs, immunotherapies, and novel strategies for advanced thyroid cancer are under investigation[122] (Table 78.6).

KEY POINTS

- Preoperative evaluation and completeness of surgical resection are important determinants of outcome, because residual metastatic lymph nodes represent the most common site of disease persistence/recurrence.
- In properly selected lower-risk patients, clinical outcomes are very similar following unilateral or bilateral thyroid surgery.
- Radioactive iodine therapy (RAI) adjuvant therapy is indicated in most high-risk patients, given significant improvement in overall and disease-specific mortality as well as disease-free survival. In a majority of low-risk patients, RAI ablation is not recommended, as its administration has no additional benefit after complete surgical resection. In patients at intermediate risk, RAI adjuvant therapy may be considered, but the decision must be individualized.
- The large majority of recurrences are detected in the first 5 years after diagnosis.
- Patients with a negative ^{131}I–whole-body scan and a positive (^{18}F)-fluorodeoxyglucose–positron emission tomography have more aggressive and less differentiated disease, with a worse prognosis.
- Advances in understanding the genomic and functional alterations contributing to the pathogenesis of thyroid cancers have opened new therapeutic opportunities and are beginning to improve patient outcomes. These include multiple kinase inhibitor drugs for each subtype of thyroid cancer, as well as the newest therapies, which are mutation-specific.

TABLE 78.6 Molecular Markers for Therapeutic of Advanced Thyroid Cancer

Genetic Alteration	Tumor Type	Available Targeted Therapeutics
BRAFV600E	PTC	Vemurafenib, dabrafenib + trametinib
HRAS	PTC, FTC, PDTC	Farnesyltransferase inhibitor tipifamib
PAXS/PPARG	FTC	Pioglitazone
ALK fusions	PTC, PDTC	Crizotinib, cerjtinib
NTRK1/2/3 fusions	PTC, PDTC	Entrectinib, larotrectinib
RET	PTC	Vandetanib, cabozantinib, selpercatinib, pralsetinib

*Approved by the US Food and Drug Administration.

PTC, Papillary thyroid carcinoma; *FTC*, follicular thyroid carcinoma; *PDTC*, poorly differentiated thyroid carcinoma.

INTRODUCTION

Two different types of cells are present in the thyroid gland: the follicular cells that secrete the thyroid hormones thyroxine (T4) and triiodothyronine (T3), and the parafollicular C cells that produce calcitonin (Ct). It is well recognized that these two thyroid cell types have unique embryonic origins, although details of their differentiation and development during organogenesis remain somewhat controversial.[1,2] Parafollicular C cells represent only 2% to 4% of the thyroid cells, which explains the low frequency of medullary thyroid carcinoma (MTC) among all thyroid cancer types.[3] However, tumors arising from the two cell types are clearly distinct entities, with different treatment and prognosis. MTC is the unique well-differentiated thyroid tumor deriving from C cells and belongs to the group of neuroendocrine tumors. In contrast, several histotypes, such as papillary, follicular, insular, poorly differentiated, and anaplastic thyroid cancer, originate from follicular epithelial cells.[4]

Because of the absence of a dedicated registry, the incidence of MTC is not defined. Its prevalence is estimated at only around 5% to 10% of all thyroid cancers and 0.4% to 1.4% of all thyroid nodules, and it is found in less than 1% of thyroids at autopsy.[5] Unlike papillary and follicular carcinomas, which are highly prevalent in females, no difference in gender distribution has been reported in MTC. The clinical appearance is mainly in the fourth and fifth decades, but there is a wide range of ages at onset.[6]

No risk factors, whether environmental or genetic, for the development of MTC have been identified, although associations with prior thyroid diseases and other unrelated disorders such as hypertension, allergies, and gallbladder disease have been reported in a metanalysis of epidemiological studies.[7]

In 1993, the pathogenesis of MTC was reported to be activation, mainly due to point mutations or small insertion/deletions, of the *RET* protooncogene.[8,9] However, it remains unclear what causes *RET* activation, which in turn sets in motion the development of MTC. *RET* activation can be responsible for both the sporadic form, which accounts for approximately 75% of cases, and the hereditary or familial form of MTC, which accounts for the remaining 25%. In sporadic cases the *RET* alteration is present only in the tumor tissue, at the somatic level, while the *RET* protooncogene alteration is transmitted in an autosomal dominant manner at the germline level.[10]

The biological behavior of MTC is much less favorable when compared with that of the other well-differentiated thyroid carcinomas, although it is not as unfavorable as that of anaplastic carcinoma.[11] While in older series a 10-year survival of approximately 50% was frequently reported for patients with MTC,[12] most recent series, including ours, show better overall survival, with 80% to 85% of patients surviving longer than 10 years, likely thanks to improvements in both diagnostic procedures and care (Fig. 79.1). Survival is dependent on several factors, such as age at diagnosis,[13] but the stage at diagnosis remains the most relevant clinical prognostic factor for survival in these patients. When an early diagnosis is made, and the tumor is still intrathyroidal, 90% of patients can survive up to 35 years.[12,14]

KEY POINTS

- MTC is a rare endocrine tumor that can be either sporadic (75%) or familial (25%). Males and females are equally affected. Children are affected only in the familial forms. No risk factors are known. An early diagnosis is desirable, since only intrathyroidal MTC can be completely cured with surgery.

CLINICAL PRESENTATION AND DIAGNOSIS

Sporadic Medullary Thyroid Cancer

The most common clinical presentation of sporadic MTC is a thyroid nodule, either as a single nodule or inside a multinodular goiter. Only in very advanced cases, diarrhea and/or flushing syndrome, due to high levels of serum Ct, can represent the first symptoms.[15] In 5% to 10% of very advanced cases, symptoms due to ectopic adrenocorticotropic hormone (ACTH) production and a consequent paraneoplastic Cushing syndrome with severe hypercortisolism can be present.[16] The simultaneous presence of a (multi)nodular thyroid and a lump in one of the laterocervical regions of the neck may lead the clinician to suspect a thyroid malignancy, but not specifically MTC.

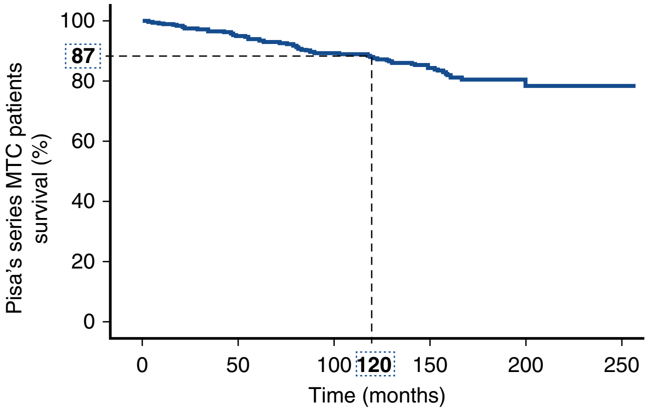

Fig. 79.1 Survival curve of 538 medullary thyroid cancer (MTC) patients followed from 2000–2018 at the University Hospital of Pisa, Italy. In this relatively recent series the survival rate at 10 years from diagnosis was 87%.

TABLE 79.1 Procedures for Calcium Stimulation Test for Serum Calcitonin in Patients with Mildly Elevated Values (Between 20 and 100 pg/mL)

Steps:

1) Patient must be weighed (do not trust what the patient says)
2) 2.5 mg of calcium element (or 25 mg of calcium gluconate) per 1 kg or 2.2 lbs of weight should be taken in a syringe
3) The volume of calcium collected in step 2 must be diluted up to 50 mL with standard saline solution
4) The intravenous infusion of the 50 mL containing calcium must be rapidly administered (in 5 minutes)
5) Blood samples must be taken at baseline before the infusion and then 2, 5, 15 minutes after the complete infusion of the 50 mL containing calcium for calcitonin measurements

NOTES Be careful to collect samples for calcitonin measurement from an intravenous access other than that used for the infusion, or aspirate at least 10 mL of liquid to be drained and then aspirate the next sample for calcitonin measurement to avoid dilution of the sample due to the liquid present in the drip tube.

A classical work-up for thyroid nodular disease is then performed.[17] Neck ultrasound (US) is the first imaging to be performed to describe thyroid nodule features. MTC nodules are usually solid and hypoechoic, sometimes with microcalcifications. A few studies have clearly demonstrated that US can only identify some malignant features and suggest a general risk of malignancy without any specificity for MTC.[18,19] Thyroid scintigraphy, either with ^{131}I or Tc99, is commonly performed only if there is a large multinodular goiter, to map the entire thyroid and the several nodules, or if the thyrotropin-stimulating hormone level is low, suggesting hyperfunction of the gland/nodule. If performed, MTC appears as a cold nodule at neck scintigraphy.

Fine-needle aspiration cytology (FNAC) is the gold standard procedure for determining whether thyroid nodules are benign or malignant. In a typical MTC cytological smear, cells are usually isolated, with shape varying from oval to round, large polygonal or spindled. Cytoplasm may be abundant or scant and usually contains acidophilic granulation visible with specific stains (May-Grunwald-Giemsa). Nuclei are frequently multiple (i.e., two or three), preferentially round, and eccentrically localized.[17] Amyloid is frequently detectable as clumps of amorphous material and revealed by Red Congo staining[20]: when present, it is highly suggestive of MTC. Immunocytochemistry for Ct and/or chromogranin, another neuropeptide secreted by MTC, is not routinely performed, but can be carried out if there is suspicion for MTC.[21,22] Despite this apparently typical MTC cytological pattern, several series have shown a high rate of failure in making a cytological presurgical diagnosis.[23,24] Missed presurgical diagnosis of MTC can lead to incorrect initial surgical treatment, which in principle should be total thyroidectomy and central neck node dissection. Recently, a multicentric international study involving 12 different referral centers across seven different continents and four nations showed that only 46% of 245 MTC cases received a correct cytological diagnosis of MTC, demonstrating that this is a worldwide pathology issue.[25]

Among other explanations, FNAC-negative results might be due to the fact that MTC could be present in a nodule not subjected to FNAC, especially when multinodular goiter is the clinical diagnosis. In these cases, serum Ct measurement is more reliable, because this hormone is elevated even in the presence of MTC microfoci.[23,26] However, there is some controversy in the different guidelines regarding routine measurement of serum Ct in all patients with thyroid nodule(s). The British Thyroid Association[27] and the National Comprehensive Cancer Network[28] share the view that serum Ct should be measured any time a presurgical diagnosis of MTC is suspected due to positive FNAC, familial history, or the simultaneous presence of other endocrine neoplasia. The American Thyroid Association guidelines for the management of thyroid nodules[29] do not recommend for or against routine serum Ct testing. In contrast, the European Thyroid Association (ETA) consensus[30] clearly states that this procedure should be applied in the work-up of all thyroid nodules, because it is more sensitive than FNAC. In 2010, a new document signed by the American Association of Clinical Endocrinologists, the Associazione Medici Endocrinologici, and the ETA was published, declaring that routine serum Ct may be useful, especially before surgery, and strongly recommending Ct measurement in certain high-risk groups.[31]

The major concerns about the routine measurement of serum Ct in all patients with thyroid nodules are related to both the possible "false-positive" cases and the "cost-benefit" analysis. There is a real risk that mildly elevated serum Ct, between 20 and 100 pg/mL, could be due to C cell hyperplasia (CCH) or other neuroendocrine tumors, or even to assay artifact rather than authentic MTC.[32,33] However, serum Ct values in this "grey zone" do raise suspicion for MTC, even though they are not diagnostic, and other diagnostic tools should be used to rule out this diagnostic doubt. Subjects with mildly elevated basal serum Ct could undergo a calcium stimulation test[34,35] following a well-defined procedure, as reported in Table 79.1. The degree of Ct increase can distinguish different clinical scenarios, because only serum Ct produced by C cells will significantly increase after stimulation, while serum Ct due to artifacts, such as heterophilic antibodies, or produced by other neuroendocrine tumors does not respond to the stimulus.[36,37] Another useful diagnostic tool to apply when serum Ct is mildly elevated is measuring Ct in the washout fluid from the needle used for FNAC.[38] This approach is of diagnostic utility to ascertain the nature not only of the thyroid nodule, if MTC is suspected, but also of neck lymph nodes, especially before thyroidectomy, to plan the surgical approach or the most appropriate therapeutic strategy. Moreover, in the presence of mildly elevated serum Ct, the pathologist can be alerted and asked to perform immunocytochemistry for Ct, which, as previously mentioned, is not a routine procedure. Although the routine measurement of serum Ct in all subjects with thyroid nodules is still controversial,[39] there is evidence that this approach allows early diagnosis and treatment, thus significantly improving the outcome of this potentially lethal disease.[40]

KEY POINTS

- Both sporadic and familial MTC commonly appears as a thyroid nodule; the cytological diagnosis of MTC is feasible in only 50% of cases. The measurement of serum calcitonin is recommended in the presence of a thyroid nodule. Mildly elevated serum calcitonin is not diagnostic of MTC but should raise the suspicion and induce the use of other diagnostic tools.

MTC, like many other neuroendocrine tumors, can produce other peptides than Ct, such as chromogranin, somatostatin, gastrin-releasing peptide, vasoactive intestinal peptide, neuron-specific enolase, serotonin, prostaglandins, and other neuroendocrine substances, but none of them are useful for presurgical diagnosis.[41] When elevated, they may all contribute to flushing and diarrhea syndrome.[42]

Serum carcinoembryonic antigen (CEA) is usually elevated when the disease is diffuse and distant metastases are present.[43] In the few cases of dedifferentiated MTC that are unable to secrete Ct, CEA becomes the serum marker of the disease.[44] Nevertheless, it is more useful in monitoring disease progression because its level increases when the disease becomes rapidly progressive.

Because at least 5% to 7% of apparently sporadic cases of MTC are indeed hereditary cases,[45,46] preoperative evaluation of both the adrenal and parathyroid morphology and function should always be performed. The familial history should also be carefully considered, with particular regard to the occurrence of pheochromocytoma (PHEO) and hyperparathyroidism (HyperPTH) in other family members. Nowadays, all subjects with MTC, independently ascertained to be sporadic or familial, must undergo *RET* genetic screening, which can be easily performed in a genetic laboratory by analyzing the sequence of *RET* gene in DNA extracted from the patient's blood or saliva.[10]

KEY POINTS

- All MTC patients must undergo the RET genetic screening, since about 8% of apparently sporadic cases are indeed hereditary. All first-degree relatives of a MTC patient carrying a germline RET mutation should be submitted to the RET genetic screening.

Hereditary Forms (Multiple Endocrine Neoplasia Type II)

In approximately 25% of cases, MTC is one of the components of multiple endocrine neoplasia type II (MEN II), which is an autosomal dominant inherited syndrome with a variable degree of expressivity and an age-related penetrance. Three different hereditary syndromes can be distinguished, depending on the involved glands (Fig. 79.2): 1) multiple endocrine neoplasia type IIA (MEN IIA), a syndrome consisting of MTC, PHEO, and HyperPTH due to parathyroid multiple adenomatosis/hyperplasia[47]; 2) multiple endocrine neoplasia type IIB (MEN IIB), a syndrome consisting of MTC, PHEO, mucosal neuromas, ganglioneuromatosis, marfanoid features, skeletal alterations, and megacolon[48]; and 3) familial MTC (FMTC), which is characterized by the presence of heritable MTC with no apparent association with other endocrine neoplasia.[49] After the introduction of the *RET* genetic screening, the relative prevalence of FMTC syndrome was found to be much higher than expected (accounting for 10%–50% of all MEN syndromes). The increase in FMTC is mainly due to the high number of apparently sporadic MTCs demonstrated to be familial cases by *RET* mutation analysis.[46]

The clinical course of MTC varies considerably in the three syndromes. It is very aggressive and almost invariably unfavorable in MEN IIB, with affected patients rarely surviving past adolescence.[48] In contrast, MTC is almost indolent in most patients with the FMTC form, and shows variable degrees of aggressiveness in patients with MEN IIA. Different types of *RET* gene mutations account for different biological behavior, and separate therapeutic protocols have been defined for the treatment of MTC occurring in the three different syndromes.[50] Between 10% and 30% of patients with MEN IIA develop HyperPTH during the third or fourth decade of life. The clinical findings are superimposable on those of the sporadic form of HyperPTH, and very often no specific symptoms are noted. Unlike the sporadic form, multiple hyperplasia or adenomatosis of parathyroid glands is most commonly found.[47,51] HyperPTH has only occasionally been reported in patients with MEN IIB.[52] Very recently, a peculiar case of simultaneous MEN IIA and IIB clinical features has been described.[53]

Approximately 50% of MEN IIA and 40% to 45% of MEN IIB patients develop PHEO, which shares the same characteristics in both syndromes. Contrary to the sporadic form of PHEO, the adrenal

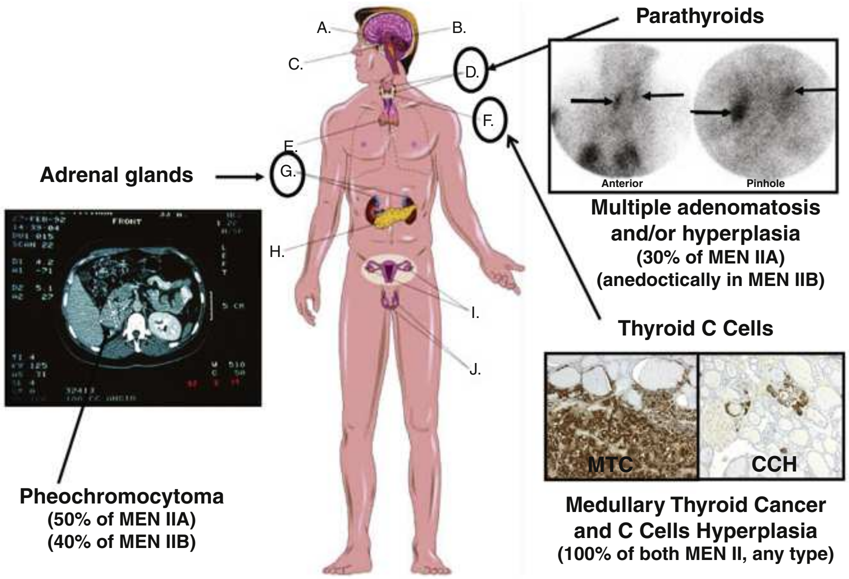

Fig. 79.2 Different endocrine glands' involvement in the three different phenotypes of multiple endocrine neoplasia type II (MEN II).

tumors seen in MEN syndromes are usually bilateral and multicentric. However, the two adrenal glands are rarely simultaneously involved, and a mean period of 10 years usually elapses between the development of the tumor in the two glands.

MEN IIB is characterized by association with mucosal neuromas, which are mainly located on the distal tongue and subconjunctival areas, and ganglioneuromatosis affecting the gastrointestinal tract, which is responsible for the very commonly seen symptom of megacolon. MEN IIB patients should be easily recognized at physical examination by the typical marfanoid habitus characterized by thin and inappropriately long extremities and pectus excavatum.[48] Thick lips and thick eyelids are frequently observed in the presence of mucosal neuromas and are usually clearly evident when the eyes and mouth are explored. Gastrointestinal disorders due to intestinal neuromas throughout the intestinal tract, including obstructive symptoms, cramping, and diarrhea, are frequently observed in early childhood. However, despite these very pathognomonic features, the diagnosis is usually late, when MTC has already spread to lung and/or liver.[54]

An association with cutaneous lichen amyloidosis (CLA), a characteristic pigmented and itchy skin lesion specifically localized in the interscapular region of the back, has been reported in less than 10% of MEN IIA families.[55] The development of CLA may precede the development of MTC. For this reason, when present it is almost invariably diagnostic of MEN IIA and may be considered a predictor of the syndrome. Four specific *RET* mutations in exon 10 (i.e., C620, C618, C611, and C609), collectively referred to as "Janus," are responsible for both MEN IIA and Hirschsprung disease. This latter syndrome is commonly due to *RET* mutations located in the first exons of the gene that inactivate the gene. Historically these mutations were believed to be able to act simultaneously as both gain-of-function mutations, responsible for the MEN IIA phenotype, and loss-of-function mutations, responsible for the intestinal aganglionosis.[56] Recently, however, it has been demonstrated that *RET* overstimulation alone is enough to cause both phenotypes.[57]

The hereditary nature of MTC may be suspected based on a positive family history (other members already affected), or based on the presence of other endocrine neoplasia (PHEO and/or HyperPTH) or other disorders (neuromas, marfanoid features, CLA). However, at least in the Pisa series,[10] index cases of 40% of all hereditary MTC kindreds presented as apparently sporadic cases, and their hereditary origin was only discovered through *RET* screening.

The clinical appearance of MTC in MEN II syndromes is that of a thyroid nodular disease, similar to that of the sporadic form, with the exception that it is usually bilateral and multicentric and is almost invariably associated with CCH.[58] Evaluation of the thyroid nodule in the hereditary form follows the same work-up as that recommended for sporadic cases, but the hereditary forms require mandatory simultaneous examination of adrenal and parathyroid glands. With a few exceptions,[59] development and diagnosis of PHEO usually follow development and diagnosis of MTC. Symptoms of PHEO are not specific and may be confused with those caused by anxiety. Hypertension is rare, especially at the beginning of the disease. The first alteration of catecholamine production is represented by an elevation of the daily urinary excretion of epinephrine, while norepinephrine usually increases only later. Nowadays the measurement of urinary metanephrines, the O-methylated metabolites of catecholamines, is used for the early diagnosis of PHEO, because they are much more stable than catecholamines.[60] Tests for metanephrines are more specific and sensitive than those for catecholamines: while normal concentrations of metanephrines exclude the diagnosis of PHEO, normal concentrations of catecholamines do not.[61] Once the biochemical suspicion of PHEO has arisen, an abdomen US with or without computed tomography (CT) and/or magnetic resonance imaging (MRI) may be useful for localization of the adrenal mass. If there is no demonstrable adrenal mass by CT or MRI, patients should undergo functional imaging, typically positron emission tomography (PET), which can be performed with different tracers (i.e., (^{18}F)-fluorodeoxyglucose, 68Ga-DOTATATE, or (^{18}F)-dihydroxyphenylalanine [DOPA]).[62]

Parathyroid glands may also be involved in hereditary MTC, particularly in MEN IIA. Both adenomas and hyperplasia may be associated with an increase in parathyroid hormone (PTH) secretion, resulting in hypercalcemia and hypercalciuria in more advanced cases.[63] The earliest serum abnormality detected is a moderately elevated level of serum PTH, with normal-high levels of serum calcium levels. A deficit of vitamin D could also be responsible for PTH increase, and for this reason its level should always be verified to exclude secondary HyperPTH due to vitamin D deficit.[64]

Once the MTC case has been proven to be hereditary, based on the presence of a germline *RET* mutation, all first-degree relatives should undergo testing to search for the same genetic alteration.[65] This procedure is fundamental for the early discovery of gene carriers who should undergo clinical and biochemical evaluation immediately after discovery of the mutation in their DNA.

Gene Carriers

By definition, gene carriers are family members of an index patient with hereditary MTC that are potentially already affected or may develop MTC in the future. The diagnosis is performed through *RET* screening of all first-degree relatives of the index case. The mutational analysis can be limited to the *RET* mutation found in the index case: informed consent must be provided for the genetic analysis, and in the case of children either both parents or guardians should sign the consent form and agree that they will inform the child at a more appropriate age about their positive or negative status as a gene carrier.[65]

All first-degree adult relatives should undergo *RET* genetic screening as soon as possible, while the timing of testing children can vary based on the type of *RET* mutation: as soon as possible if the mutation is the M918T mutation typical of MEN IIB, before 5 years of age if the mutation involves a cysteine residue, particularly at codon 634, and even later in cases with any other type of non-cysteine *RET* mutations.[50]

Once the gene carrier has been identified, the diagnostic procedure involves a thyroid neck US and a serum Ct measurement. Some family members will already be unknowingly affected and must be immediately treated, while others will still be negative for both parameters. The timing of total thyroidectomy in these latter cases should be personalized, taking into account the type of *RET* mutation and also the levels of serum Ct.[50,66]

In the 1990s, soon after the discovery of the pathogenic relationship between the presence of a germline *RET* mutation and the development of MTC, prophylactic thyroidectomy was suggested for all gene carriers of any age.[67] Over the years, increasing knowledge of the aggressiveness of different mutations and the awareness that serum Ct highly correlates with the presence of MTC led to rethinking of this approach and the development of a more relaxed algorithm for treatment of these subjects, who can safely undergo early, rather than prophylactic, thyroidectomy.[65] Annual evaluation of basal serum Ct and a neck US should be performed, taking into account that only microMTC and/or CCH, with no evidence of metastatic lymph nodes, have been reported for serum Ct levels less than 30 to 40 pg/mL in large series of gene carriers.[66,68] In this regard, it is worth noting that central neck compartment dissection can be avoided in gene carriers with serum Ct les than 30 to 40 pg/mL who undergo thyroidectomy, especially children, thus reducing the risk of postsurgical hypoparathyroidism.[50]

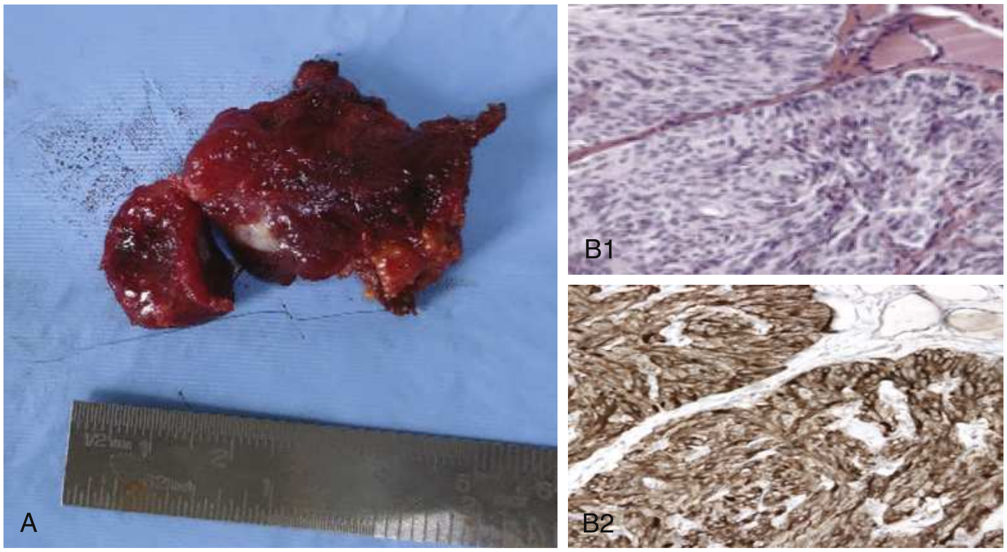

Fig. 79.3 Macroscopic (**A**) and microscopic (**B1–2**) histology of medullary thyroid cancer. **A,** The tumor appears as a solid and compact, red mass. **B1,** Hematoxylin-eosin microscopic appearance of medullary thyroid cancer. **B2,** The same section after calcitonin immunohistochemistry.

KEY POINTS

- Prophylactic thyroidectomy are not mandatory in gene carriers with no evidence of MTC, especially in children. Serum calcitonin and the type of RET mutation should guide the timing of thyroidectomy.

PATHOLOGY AND PATHOGENESIS

Histology

The macroscopic histological appearance of MTC is that of a solid and compact, red or calcareous-white nodule (Fig. 79.3A). Microscopically it is pleiomorphic, with spindle-shaped or rounded cells typically organized in a nested pattern (Fig. 79.3B1–2). Nuclei are uniform, mitoses are rare, and the cytoplasm is characterized by the presence of secretory granules. Amyloid substance can be present among MTC cells, and when present, it allows the diagnosis. Sometimes MTC can be erroneously diagnosed as anaplastic thyroid carcinoma, Huerthle cell carcinoma, or insular differentiated thyroid carcinoma, especially if pseudopapillary aspects or giant cells are present. Positive immunohistochemistry for Ct, and also for chromogranin A and CEA, is undoubtedly diagnostic of MTC.[69] The histological description of MTC should include the number and distribution of tumoral foci. CCH, either diffuse or focal, should also be reported because, although it is the histological hallmark of the hereditary forms, it is also present in approximately 13% of sporadic cases.[70] With the exception of the prevalence of CCH, no other major histological differences have been described between the sporadic and the hereditary forms of MTC.

Genetics

In 1994, after discovering the transforming role of the *RET* oncogene, the correlation between the presence of a germline activating mutation of *RET* and the hereditary form of MTC was demonstrated in almost 500 kindreds affected by MEN II or FMTC.[71] In the same study, somatic *RET* mutations were reported in approximately 40% of sporadic MTCs. Thereafter, both *in vitro* and *in vivo* studies confirmed the driver role of *RET* mutations in the development of MTC.[72,73]

Germline *RET* point mutations are mainly localized in exons 10 to 11 and 13 to 16, but other rare mutations have been reported in other exons, such as 5 and 8, and all of these exons must be analyzed as part of the genetic screening procedure.[65] A significant genotype–phenotype correlation has been reported over the years, with some *RET* mutations being almost exclusively associated with a specific MEN II syndrome.[74] With a few exceptions, known as "variants of unknown significance,"[75] the penetrance of *RET* mutations is complete, in that all gene carriers will develop the disease sooner or later. In contrast, the level of expressivity is different, in that MTC due to different *RET* mutations can have different degree of aggressiveness based on the transforming ability, which is the highest for the M918T mutation.[75] According to these differences, the *RET* mutations have been distinguished in three risk levels (i.e., moderate, high, highest) of aggressiveness, which should be taken into account to identify the right time for the surgical treatment of *RET* gene carriers.[76]

Somatic *RET* mutations are mainly concentrated in exon 16, and have been reported in other exons in only a few cases. Moreover, *RET* somatic mutation prevalence is significantly higher in larger MTC tumors than in smaller MTC tumors,[77] and is particularly high in advanced and progressive MTC.[78] Although not yet introduced into routine clinical practice, it would be valuable to know if a patient with sporadic MTC is carrying a *RET* somatic mutation, as mutated cases have a worse prognosis[79]; thus, a more aggressive therapeutic strategy or a more stringent follow-up could be provided for these patients. Moreover, new *RET*-targeted therapies are under development and require the characterization of the molecular profile of the MTC.[80,81]

RAS oncogene somatic mutations, in particular in *H-RAS* and *K-RAS*, are present in approximately 10% to 20% of cases of sporadic MTC, and they are mutually exclusive with *RET* mutations.[82] No other driver mutations have been discovered in *RET*- and *RAS*-negative MTCs, even when tissues were analyzed with next-generation sequencing techniques.[83,84] These studies did identify very rare mutations, but their prevalence was so low that they are considered "private" mutations that are likely relevant only in that specific case.[85] A similar finding has been reported for hereditary cases: the *ESR2* gene, which encodes the beta subunit of the estrogen receptor, has been found to be mutated in two individuals with FMTC but not in their unaffected relatives. However, the same *ESR2* mutation was not found in other

RET-negative FMTC kindreds, thus suggesting that it was a "private mutation" of the first family analyzed.[86] The next challenge is to identify the driver mutations in both *RET*-negative familial cases and *RET*- and *RAS*-negative sporadic cases.

KEY POINTS

- With a few exceptions, hereditary MTC are positive for a germline RET mutation. Almost 50% of sporadic MTC are positive for RET mutation at somatic level. Another 30% are positive for H- or K-RAS somatic mutations. The remaining 20% of sporadic cases are negative for any other known oncogene.

INITIAL THERAPY

Total thyroidectomy and central node compartment dissection is the minimal surgical treatment, even in intrathyroidal cases. The need for total thyroidectomy is related to the multicentricity and bilaterality of the MTC, which occur in 17% and 5.6%, respectively, of cases with the sporadic form.[87] Moreover, CCH, which is a preneoplastic lesion, is almost invariably associated with the hereditary form of MTC (75%) and, to a lesser extent, with the sporadic form (13%).[70] An additional factor in favor of total thyroidectomy is the fact that, as mentioned above, 5% to 7% of apparently sporadic cases are in fact hereditary forms and almost invariably have bilateral disease.[45,46]

Total thyroidectomy and central neck dissection will be extended to the laterocervical compartment(s) if metastatic lymph nodes are recognized in these regions. For this reason, an accurate neck US should be performed in order to identify suspicious metastatic lymph nodes to be subjected to FNAC, as well as measurement of Ct in the washout fluid from the needle used.[38] However, not all authors agree with this strategy, and some prefer to plan extension of surgery based on the presurgical Ct serum level, independent of the results from the neck US.[88] In this regard it is worth noting that, unfortunately, when the MTC has metastasized to neck lymph node, especially to the laterocervical ones, it is very difficult to achieve definitive surgical and biochemical cure of the disease.[89]

Measurement of serum CEA is also indicated in the preoperative phase, because elevated levels are strongly suggestive of advanced disease. Cases with advanced local disease demonstrated by neck US and associated with elevated serum CEA levels should be studied with computerized tomography (CT) scan to better evaluate the local extension of the tumor and to verify the relationship of the disease with the gross veins, trachea, and esophagus and plan the most appropriate surgical treatment.[50]

KEY POINTS

- The initial therapy consisted of at least total thyroidectomy and lymph node dissection of the central neck compartment. The lymphadenectomy of the latero-cervical compartments should not be prophylactically performed but only when metastatic latero-cervical metastatic lymphnodes are present at the time of the diagnosis or when presurgical serum calcitonin is highly elevated.

Surgical removal of the primary tumor and neck lymph nodes metastases is also recommended in cases with distant metastases already present at diagnosis.[50] In these latter cases, and in cases with tumor invasion of the vital structures of the neck, a multidisciplinary meeting must be held before surgery to plan for additional therapies.[90]

Before surgery, an evaluation of the adrenal gland function to exclude the presence of a PHEO must always be performed, except in genetically documented sporadic MTC. The reason for this procedure is in the need to perform the PHEO excision before the MTC surgery, in cases of the simultaneous presence of both tumors, to avoid unexpected hypertensive crisis during the MTC surgery.

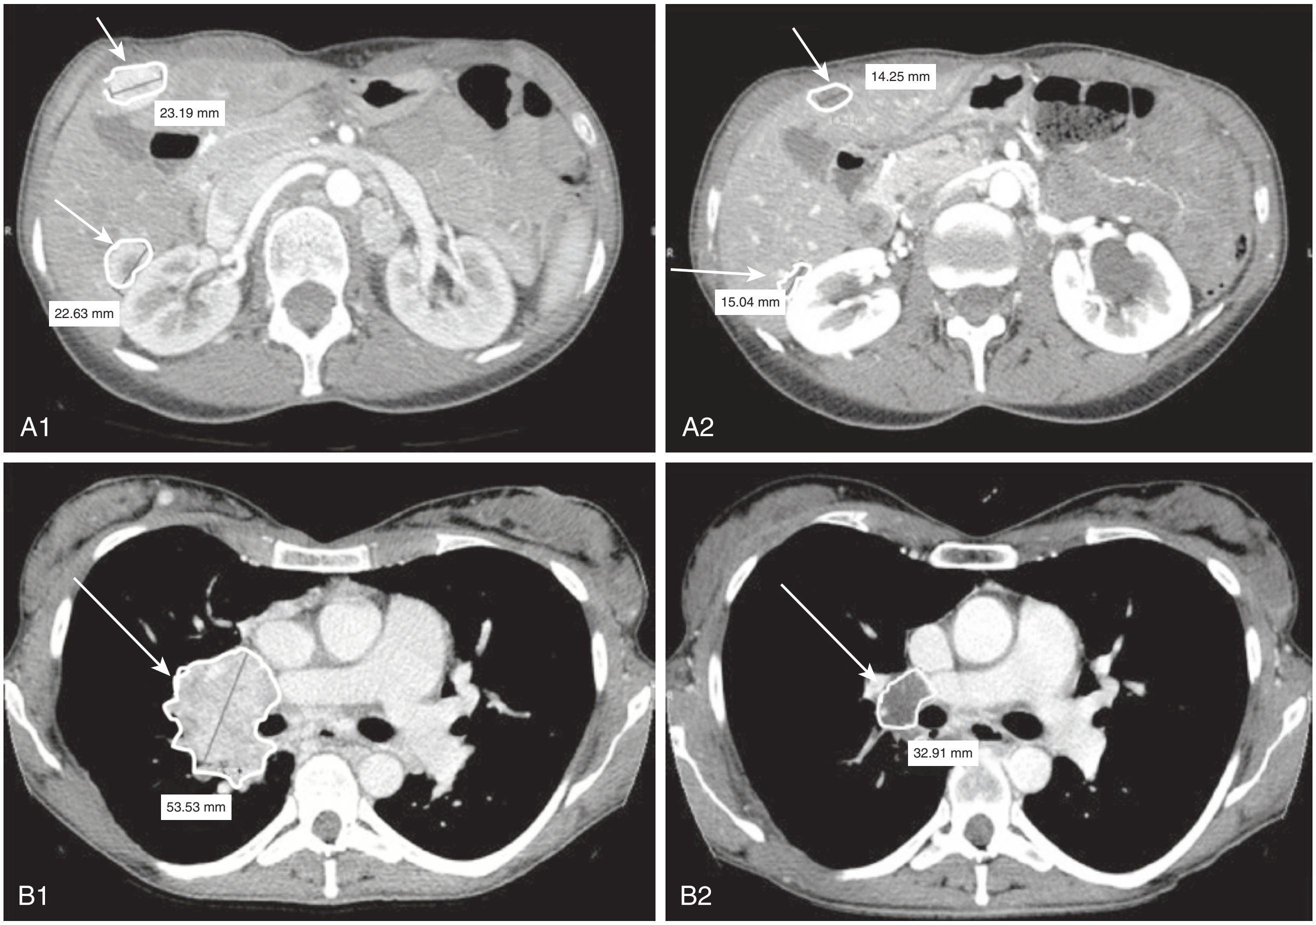

Fig. 79.5 Two cases of medullary thyroid cancer metastatic disease treated with vandetanib (**A**) and cabozantinib (**B**). **A,** Liver metastatic lesions *(arrows)* before vandetanib treatment (**A1**) and after 6 months of therapy (**A2**). **B,** Right metastatic hilar lymph node *(arrows)* before cabozantinib treatment (**B1**) and after 2 months of therapy (**B2**). In both cases, significant shrinkage of the lesions is visible, and their devascularization is demonstrated by the significantly lower density of the lesions after the treatments.

POSTSURGICAL FOLLOW-UP

The first evaluation after surgery should be performed 3 months after the surgical treatment, including physical examination, neck US, and measurement of serum free T3 (FT3), free T4 (FT4), thyroid-stimulating hormone (TSH), Ct, and CEA. Measurement of FT3, FT4, and TSH is requested for monitoring levothyroxine replacement therapy. Serum Ct and CEA measurement and neck US are necessary for the follow-up of MTC. Due to the relatively long half-lives, if performed too early, serum values of Ct may be misleading, especially if a high serum concentration was present preoperatively.[91]

According to the results of this first evaluation after the initial therapy, MTC patients may either be classified as cured or still affected by either biochemical disease or structural disease. The timing and the type of the following evaluations depend highly on the results from this first evaluation (Fig. 79.4).

Follow-Up of Cured Medullary Thyroid Cancer Patients

Cured patients have a postsurgical Ct less than 10 pg/mL, a negative neck US, and low-normal CEA values. These patients have a 10% risk of recurrence during follow-up that becomes 3% in those patients who have both postsurgical basal and peak Ct after calcium stimulation of less than 10 pg/mL.[92] Patients with a negative stimulation test should be reevaluated every 12 to 18 months, with the aim of early interception of rare, but possible, recurrence.[50] In patients with undetectable levels of serum Ct, measurement of CEA is not necessary (Fig. 79.3A).

KEY POINTS

- After the initial treatment patients can be cured or persistently affected. In the latter case they can be either biochemically or structurally affected. Serum calcitonin and carcinoembryonic antigen (CEA) doubling times are fundamental for planning the type and timing of the imaging techniques to be performed for following the development of the disease.

Follow-Up of Patients with Biochemical Persistent Disease

Patients with biochemical persistent disease are those who show a postsurgical basal Ct greater than 10 pg/mL in the absence of any structural disease as assessed by neck US, CT scan, and, whenever possible, DOPA PET/CT. These patients should be monitored with periodical measurements of serum Ct and CEA (every 6–12 months), because increasing levels are strongly suggestive of progressive disease.[43,93] In most cases, the challenge is to find the source of production of Ct and CEA. This is particularly true in MTC cases with serum Ct less than

150 pg/mL, which are frequently negative on any type of imaging.[94] An accurate neck US is the first localization technique to be performed, due to the high frequency of local recurrence and cervical node metastases. Total-body CT scan and bone scintigraphy are also suggested in the follow-up of a MTC patient with detectable and increasing values of serum Ct. Other functional imaging, and in particular DOPA PET/CT, may be useful for identifying micrometastases not detectable with other techniques.[95] Because a detectable serum Ct level is compatible with long-term survival, during which Ct and CEA may remain stable with time or slowly increase, the most widely accepted therapeutic strategy in these patients is that of "wait and see," thus postponing any type of therapy until structural disease is detected[96] (Fig. 79.4B).

Follow-Up of Patients with Structural Disease

Approximately 10% of MTC patients already have distant metastases at diagnosis that will not be cured by thyroid surgery. Another 10% of those with initial biochemical disease will sooner or later develop local or distant metastases. These patients must be followed up with 6-month evaluations of serum Ct and CEA and calculation of their doubling time. A rapid increase in serum Ct and/or CEA is a poor prognostic factor both for recurrence and death, especially if the doubling time is less than 0.5 to 1 year.[97] A poor prognosis for survival has been recently demonstrated for serum carbohydrate antigen 19.9, particularly in advanced MTC.[98] In this event, imaging evaluations must be intensified to verify the progression of the disease and to decide if it is time to start active therapy.[99]

OTHER THERAPIES

Patients with metastatic disease can be treated with other therapies, both for symptomatic reasons and/or for the progression of the disease. In this latter case the progression should be calculated according to the Response Evaluation Criteria in Solid Tumors (RECIST)[100]: if progression of the disease is documented according to these criteria, therapeutic intervention should be started. However, if progression is present but with a slow growth rate, the indication is to wait and see. If the progression is of a single lesion or of multiple lesions in the same organ, local therapy can be applied, while if the progression is of several lesions and in different organs, systemic therapy should be initiated.[101]

Local Treatment of Recurrent or Persistent Neck Disease

Surgery. The regional lymph nodes of the neck and mediastinum are the most frequent sites of persistent or recurrent disease. In these cases, a second surgical treatment with curative intent is desirable, and to this purpose an extensive modified neck dissection involving microdissection of all node-bearing compartments is recommended. Although only less than 10% of patients affected by MTC with extrathyroidal invasion can be cured by a second surgical treatment, cervical reexploration is safe, and in selected patients may limit MTC progression.[102]

A second surgery on the neck could be also indicated for palliative, other than curative, intent, for example in patients with compressive symptoms who can benefit from surgical debulking.[103] Similarly, a second surgical treatment might be performed for symptomatic lesions or when their growth may cause significant morbidity, as may happen for lymph nodes of the mediastinum adjacent to the great vessels, tracheoesophageal groove, carotid sheath, and brachial plexus.

External Radiotherapy. External radiation therapy (ERT) after thyroidectomy and node dissection is not generally recommended on a prophylactic basis in MTC patients, and the procedure should be reserved for patients with local aggressive disease that is either recurrent or persistent after the first surgery. Although MTC has very low sensitivity to ERT, there is evidence of a potential benefit from radiotherapy in terms of a lower risk (from 2- to 4-fold) of further progression in patients with residual disease.[104] In patients who have undergone a less aggressive primary resection, ERT should be postponed to a second surgical treatment.

TABLE 79.2 **Possible Types of Local Treatments to Be Considered in Advanced Cases of Medullary Thyroid Cancer Before Starting Systemic Therapy and to be Chosen on the Basis of Both the Localization of the Growing Lesion(s) and Local Expertise**

Example of Growing Lesions	Type of Local Treatment
Isolated growing lesions in the lung, bone, liver	Surgery or thermal ablation: the latter can be performed by radiofrequency ablation, laser ablation, or cryoablation, according to local experience
Vegetating tumor tissue inside trachea or bronchus	Endotracheal/bronchial laser removal
Single, small brain metastases	Radiosurgery or stereotaxic ablation
Multiple growing brain metastases	Whole-brain irradiation for stabilization
Painful bone metastases	Antalgic external radiotherapy
Growing neck and/or mediastinal lymphnode metastases not more treatable with surgery	Palliative external radiotherapy
Multiple liver metastases	Intraarterial chemotherapy or intraarterial radioembolization

Radiofrequency and Laser Thermal Ablation. While the safety and efficacy of both laser ablation and radiofrequency thermal ablation (RFA) have been widely demonstrated in the treatment of benign thyroid nodules, evidence regarding local tumor control of thyroid malignancies is still limited. However, preliminary results are encouraging, and image-guided thermal ablation techniques can be considered a valid alternative to surgery for the treatment for recurrent thyroid cancers.

Thermal ablation is based on the use of electromagnetic waves or lasers that produce a high degree of heat. A needle-like RFA probe is introduced in the tumoral mass, and the radiofrequency waves passing through the probe increase the temperature within tumor tissue, resulting in destruction of the tumoral tissue.[105,106] Similarly, when the laser light hits the target, a local increase in temperature occurs, causing permanent damage such as coagulative necrosis and tissue carbonization/vaporization. Both techniques are performed under US guidance, which allows real-time monitoring of the procedure. Thermal ablation is of particular utility when the lesion to be treated is the only site of disease or the only one, among others, that is growing, and surgical treatment cannot be performed, as frequently happens in local para- or retrotracheal recurrence of MTC.

Treatment of Distant Metastases. Local treatments, as described earlier, are also indicated for single, growing, distant metastatic lesions or, if multiple, when only one of them represents a clinical problem, such as pain, local compression of other organs, risk of fracture, or risk of blood invasion. The possibility of local treatment should be always considered before starting systemic therapy, which should be reserved for cases with multiple metastatic lesions that involve multiple organs and are actively growing.[107] As shown in Table 79.2, local treatments can vary according with the site and the number of the metastatic lesions, and decision-making requires the involvement of a multidisciplinary team.

TABLE 79.3 More Frequent Adverse Events Reported in Clinical Trials of the Currently Available Tyrosine Kinase Inhibitors Used for the Treatment of Advanced and Progressive Multimetastatic Medullary Thyroid Cancer

Adverse Events (All Grade)#	Vandetanib (%)	Cabozantinib (%)	Selpercatinib (%)	Pralsetinib (%)
Hypertension	32	33	43	40
Diarrhea	56	63	38	34
Skin rash*	45	19	NR^	24
Anorexia	21	46	NR	15
Fatigue	24	41	38	38
Nausea	33	43	35	17
Weight loss	10	48	NR	NR
QT prolongation	14	NR	19	NR
Hand-foot syndrome	NR	50	NR	NR
Increased SGOT	NR	86	57	69
Increased SGPT	NR	86	51	43

[#] For selpercatinib and pralsetinib, the majority of adverse events were grade 1 or 2.

*Rash includes dermatitis, dermatitis acneiform, eczema, palmar-plantar, erythrodysaesthesia syndrome, erythematous rash, macular rash, maculo-papular rash, papular rash, and pustular rash.

NR, Not reported; *SGOT*, serum glutamate oxaloacetate transaminase; *SGPT*, serum glutamate-pyruvate transaminase.

KEY POINTS

- Advanced MTC should be treated when progressing according to RECIST or according to clinical judgment. If the disease progression is related to one single lesion or to several lesions but belonging to the same organ, local therapies should be preferred.

Systemic Targeted Therapies. Once generalized disease progression has been documented according to RECIST, systemic therapy must be started. Traditional chemotherapy for advanced and progressing MTC has shown limited and temporary response rates in several small series published to date.[108] Chemotherapy is no longer used in progressing MTC, and, if ever used, is reserved for those MTC patients who, for any reason, cannot be treated with tyrosine kinase inhibitors (TKIs), which represent the first choice for systemic therapy.[101]

At the present, there are two available oral drugs belonging to the TKI family: vandetanib and cabozantinib. They were approved by both the US Food and Drug Administration (FDA) and the European Medical Agency (EMA) after the results of the phase III clinical studies ZETA and EXAM,[109,110] which both demonstrated a significant increase in progression-free survival (PFS) compared with placebo.

Both vandetanib and cabozantinib are small molecules able to block, with different activities and different patterns, multiple tyrosine kinases.[111] Among these anti–tyrosine kinase activities, both of them are able to block the constitutively activated Ret receptor. The drugs should be initiated with evidence of disease progression according to RECIST or, in very advanced cases, based on clinical judgment. Although the two drugs are both citostatic more than citotoxic, a significant srinkage of the metastatic lesions can be observed (Fig. 79.5). Vandetanib can be used successfully also in symptomatic patients and those with ectopic Cushing syndrome.[112,113]

The choice to start with one drug or another is strictly dependent on the local availability of the drug, as not all countries have approved or reimburse the use of both drugs. However, if both vandetanib and cabozantinib can be prescribed, the choice must be dictated by the patient's clinical features, location of metastatic lesions, and drug characteristics. According to the results of the phase III studies,[109,110] cabozantinib exhibits more rapid action but is associated with more severe adverse events (AEs). Taking into account these factors, cabozantinib should be preferred when rapid shrinkage of the metastatic lesion is needed, and when this need is sufficient to run the risk of AEs. In the phase III EXAM study, patients could be enrolled even if previously treated with other TKIs, and the results showed that cabozantinib works similarly both as first- and second-line treatment in terms of prolongation of PFS. Based on this result, vandetanib should be used as first-line therapy to reserve the possibility of using cabozantinib as second-line therapy when, for any reason, vandetanib needs to be stopped. Vandetanib, but not cabozantinib, has been successfully tested in children affected by advanced and metastatic MTC in MEN II, mainly MEN IIB.[114] The outcomes in these children demonstrated that vandetanib can be safely and satisfactorily used.[115] Moreover, several reports have shown that ectopic ACTH secretion and paraneoplastic Cushing syndrome are completely reverted and cured by vandetanib.[112,113,116] Vandetanib, but not cabozantinib, can result in prolonged QTc (>440 ms in adult males and >460 ms in adult females)[117]; this adverse effect can be life-threatening, thus cabozantinib is the first-choice drug in patient with QTc values that are already prolonged before starting therapy.

Both drugs can induce very similar AEs, but the prevalence varies (Table 79.3), and this must be considered, as well patient co-morbidities, when deciding which drug should be started first. Although both drugs result in a a significant prolongation in PFS, to date there is no evidence for an increase in overall survival. However, exploratory analyses suggest that patients with *RET* M918T–positive MTC may benefit more than those with *RET* M918T–negative from treatment with cabozantinib.[118]

As with all TKIs, both vandetanib and cabozantinib should be continued until there is evidence of clinical benefit. The reason for this is that they are cytostatic and not cytotoxic, meaning they can block cell proliferation and growth but cannot kill tumoral cells. Nevertheless, two studies and real-life experience have demonstrated that the objective response of metastatic lesions can be significant, although complete response has never been observed.[109,110]

Both drugs can induce several AEs, sometimes of grade 3, and their management is fundamental for success of the treatment. They must be early recognized and immediately treated either with other drugs if possible (i.e., hypertension) or by reducing the daily dose of the drug (i.e., fatigue or anorexia). A multidisciplinary team at a referral center should take care of these patients during all treatment follow-up.

The development of drug resistance and the consequent escape phenomenon are the major concerns associated with this treatment. Once the disease shows progression under treatment, clinicians must decide to continue or to stop the drug. Further studies analyzing the possibility of using the two drugs in an alternating modality, or combined with each other or with other drugs, are an important challenge for the future.

A new generation of TKIs that are much more specific for *RET* mutations has been developed in recent years. LOXO-292, also known as selpercatinib, and BLU-667, also known as pralsetinib, have been successfully tested in phase I/II clinical trials and, after publication of the results,[80,81] both were recently approved by the FDA and are under evaluation from the EMA. They are both potent KDR/VEGF2-sparing *RET* inhibitors with preclinical specificity for *RET* alterations, both gene fusions and point mutations, including the V804M mutation, which showed *in vitro* resistance to vandetanib.[119] These results were further confirmed in animal models and clinical studies,[120,121] in which relevant tumor shrinkage was shown. Interestingly, in mouse models, selpercatinib showed antineoplastic activity against brain metastasis too.[120] Both drugs have a very good safety profile, with few AEs that are generally of low grade (Table 79.3). Whenever possible, these drugs should be the first choice, but their prescription is determined by the presence of a *RET* mutation, either somatic or germline; thus, 15% of cases of advanced MTC cannot be treated with any of these drugs.

When no other drugs are available, other TKIs that have shown positive results in phase II clinical trials[122-127] or in real life[128,129] can prescribed "off label." They may be used also as second- or third-line treatments after cabozantinib and/or vandetanib, especially in MTC with no evidence of *RET* mutations.

KEY POINTS

- Nowadays two tyrosine multikinase inhibitors, vandetanib and cabozantinib, are available for the systemic therapy. In the near future a second generation of RET-specific inhibitors, selpercatinib and pralsetinib, will likely reach clinical practice.

Radionuclide Systemic Therapies. Treatment with radioactive elements has been widely explored in the past, including treatment with radioiodine (^{131}I) linked to meta-iodobenzylguanidine[130] and anti-CEA targeted radioimmunotherapy, but with very limited results, and nowadays these approaches are not used or are only used in cases that are refractory to any other type of systemic therapy.

MTC is a neuroendocrine tumor, and 30% to 50% of cases express somatostatin (SMS) receptors, as documented by octreoscan and by 68Ga-DOTATATE PET/CT.[131,132] A few studies have been reported with promising, but not enthusiastic, results.[133] However, a hypothesis to explain this failure could be the too-advanced disease status at the time of the treatment, thus suggesting of that further studies should be performed with less-advanced cases. Several radiolabeled SMS analogs have been explored as potential therapeutic agents. Most studies of radionuclide therapy in MTC have investigated the use of SMS analogs labeled with the radionuclide(s) 90 yttrium (^{90}Y) and/or 177 lutetium (^{177}Lu).[133-136] The use of 111 indium (^{111}In) was also evaluated.[137] A greater than or equal to 50% decrease in Ct values compared with baseline in one third of patients treated with ^{90}Y[135] and ^{177}Lu[133] has been reported, while others demonstrated a relevant reduction in tumor growth rate. Despite these promising results, these treatments are not yet part of clinical practice.

At present, radionuclide therapy is reserved for those cases that, for any reason, do not respond to or cannot be treated with targeted therapy. However, several ongoing clinical trials (NCT00002947, NCT03647657, NCT02088645, and NCT04106843) should provide more reliable data in the near future.

Other Systemic Therapies. Over the years, different types of octreotide, from the native to the long-acting analogs, have been tested as potential therapeutic agents for MTC. In many cases, a significant reduction in serum Ct has been demonstrated,[138] but no evidence of a parallel relevant reduction in structural disease has been shown. In patients with severe diarrhea that is uncontrolled with any other conventional drug, the use of SMS long-acting analogs can be considered.

Although there are no specific studies of MTC series, treatment with either bisphosphonates or the receptor activator of nuclear factor kappa-B ligand (RANKL) inhibitor denosumab has been recognized as valid in the treatment of bone metastases.[76] This therapeutic procedure has been demonstrated to be effective in controlling bone pain and delaying the occurrence of skeletal-related events in patients with bone metastases due to differentiated thyroid cancer.[139] Both pamidronate and zoledronate are administered intravenously on a monthly basis, while denosumab is administered subcutaneously every 4 weeks. The side effects of these potent antiresorptive agents, although rare, include osteonecrosis of the jaw,[140] atypical subtrochanteric fractures,[141] and hypocalcemia, and must be carefully taken into consideration before starting the therapy and during long-term treatment.

CONCLUSIONS

Medullary thyroid cancer is a rare cancer with a relatively poor prognosis, and the only possibility of achieving a definitive cure is an early diagnosis when the tumor is still intrathyroidal. The routine measurement of serum Ct in all patients with thyroid nodules is still debated.

In 25% of cases, MTC is inherited as an autosomal dominant disease, and children can be affected. *RET* genetic screening is recommended in this latter form to identify gene carriers early and adequately plan the timing of surgery.

Initial therapy is complete removal of the thyroid gland and central node neck dissection, but only one third of patients will be definitively cured by this procedure. Patients must be followed up over the years for the possibility of recurrences, especially when serum Ct is still detectable after surgery. Several modalities of local and systemic therapies are available for metastatic progressive lesions. Nowadays, several drugs belonging to the TKI family are available, and others are under development.

MTC patients should be followed in referral centers and by a multidisciplinary team that should be led by an expert endocrinologist, especially when the disease involves other endocrine glands, as occurs in the familial forms.

PRESENTATION

Epidemiology

Undifferentiated (i.e., anaplastic) thyroid carcinoma (ATC) comprises a small percentage of all thyroid malignancies worldwide. In a review of frequency in 15 countries, the median percentage of ATC out of all thyroid cancer cases was 3.6% (range: 0.6%–9.8%), with a decrease in several countries after dietary iodide was increased.[1,2] In the United States, the estimated number of all new thyroid cancer cases in 2021 will be 44,280 (32,130 female and 12,150 male) and estimated deaths to be 2,200 (1,150 female; 1,050 male). ATC occurs in only 1% to 2% of thyroid cancers in the United States,[3] but accounts for almost half of thyroid cancer-related deaths, reflecting the extremely aggressive behavior of ATC. The incidence varies slightly among racial/ethnic groups in the United States, occurring in 0.6% of all thyroid cancers in Hispanic Whites, 1.0% in Asian-Pacific Islanders, 1.1% in non-Hispanic Whites, 1.3% in Native Americans, and 1.8% in Black patients.[1]

Clinical Characteristics

In a review of 44 series in 2016 comprising 2881 patients, 1898 (66%) were female, and 983 (34%) were male.[1] Although patients ranged in age from 15 to 98 years, ATC is primarily a disease of older persons, with mean age of 66.5 years (n =19 studies) and median age of 69 years (n = 26 studies). The median size of the primary tumor was 6.8 cm (range: 0.5–25 cm). ATC could arise *de novo* but was more likely to develop in patients who had a longstanding goiter or, in 30% of cases (range: 3%–58%), coexist with differentiated thyroid cancer. Distant metastases were present at initial diagnosis in 42% of patients (range: 11%–90%). Five of the 44 reports identified the causes of death: local disease in 15% (range: 5%–37%) of patients, distant metastases in 59% (range: 12%–68%) or both local and distant disease in 26% (range: 25%–51%). Since that review, ten additional studies (comprising 1953 patients) have reported similar results, mirroring the characteristics observed in the earlier reports.[4-13]

Clinically, the most frequent initial symptom is a rapidly enlarging neck mass, observed in 86% of studies (range: 46%–100%).[1] The mass is often invasive, leading to destruction to nearby structures, including the trachea, esophagus, cervical vessels, and recurrent laryngeal nerves, resulting in hoarseness or dysphonia (33% of cases), dysphagia (38%), dyspnea (27%), pain (16%), and, less frequently, cough, hemoptysis, or superior vena cava syndrome (10% or less). Distant metastases at presentation are detected most often in the lungs (37%), followed by mediastinum, liver, bone, brain, kidneys, heart, and adrenal glands. At autopsy, distant metastases are noted at two to four times the clinical detection rate.[1]

DIAGNOSIS

Biopsy

KEY POINTS

- Anaplastic thyroid cancer is rare, accounting for approximately 3.6% of all thyroid cancers, and is extremely aggressive.
- Median age of diagnosis is approximately at 66 years with median tumor size of 6.8 cm.
- Patients most commonly present with a rapidly enlarging neck mass, with symptoms related to extent of disease involvement.

Fine-needle aspiration biopsy and cytology can be attempted first but has a higher nondiagnostic rate than in other thyroid malignancies because of the undifferentiated nature of the cells, as well as extensive necrosis and infiltration of tumor macrophages. If unsuccessful, then expeditious core tissue biopsy or possibly even surgical biopsy may be necessary. ATC has no histologic features of thyroid tissue, although it may coexist with differentiated thyroid cancer. Several other tumors should be considered in the differential diagnosis, however.

Histopathology Subtypes

The major subtypes of ATC include sarcomatoid (i.e., spindle cell), pleomorphic giant cell, and epithelial (i.e., squamoid) (Fig. 80.1).

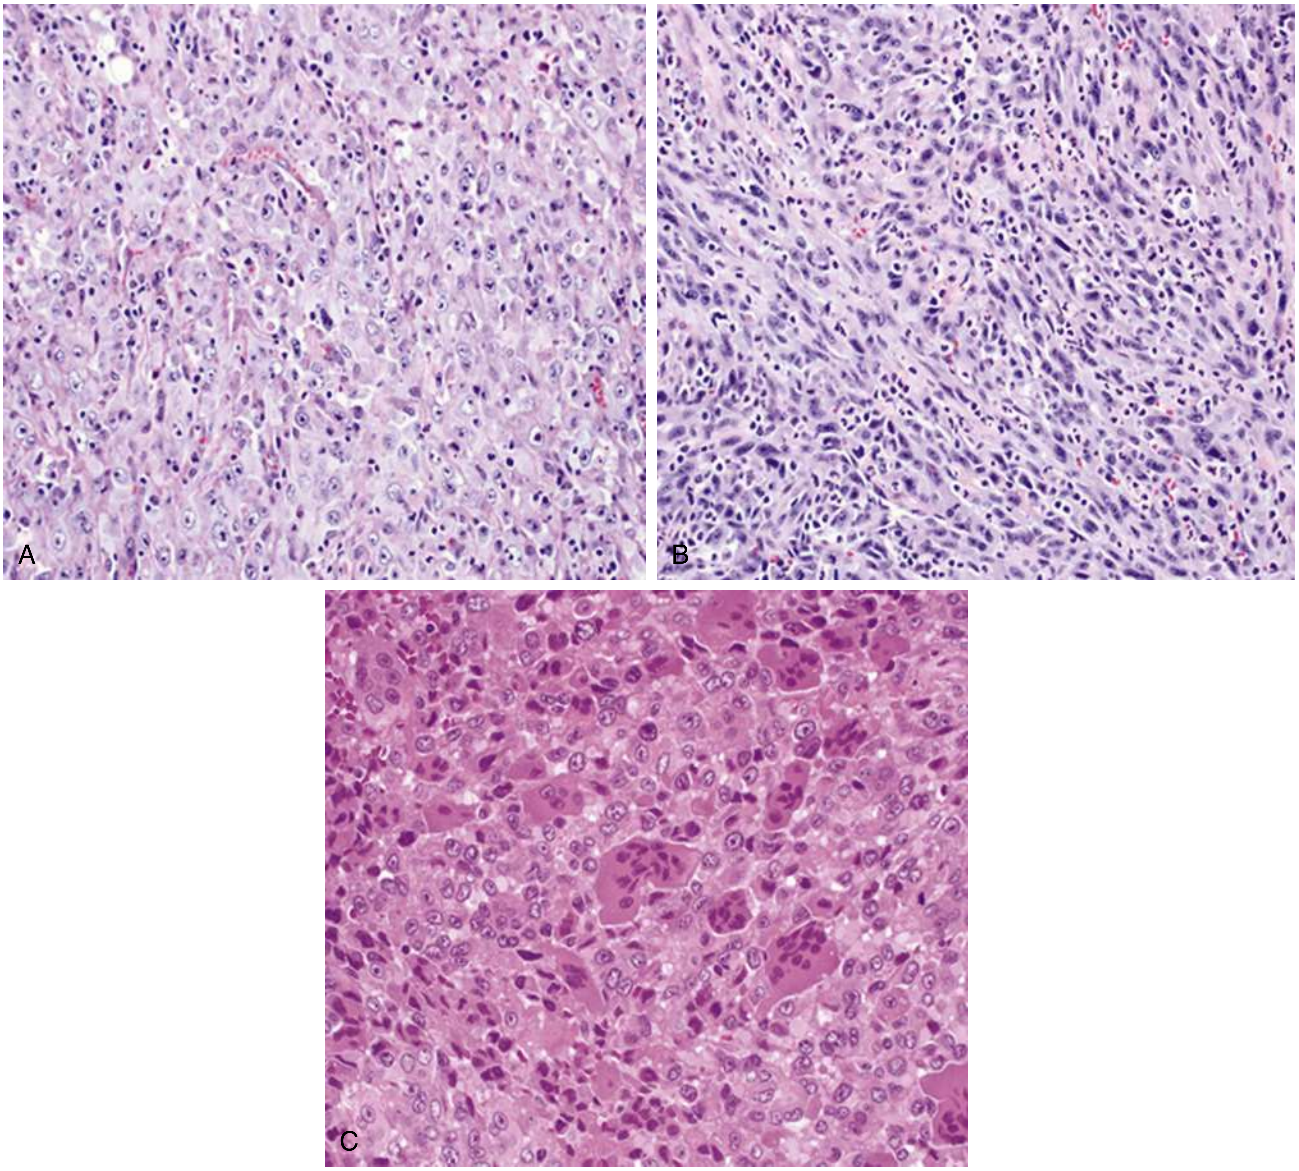

Fig. 80.1 Histologic subtypes of anaplastic thyroid carcinoma. Spindle cell variant (**A**), epithelioid variant (**B**), and giant cell variant (**C**).

These subtypes are often mixed. Other rare variants include paucicellular, rhabdoid, osteoclastic, angiomatoid, lymphoepithelioma-like, and small cell.[9,14-18] The specific histotype may influence survival, as long-term survival (>1 year) is significantly more common in tumors with epithelial or squamous cell component, and short-term survival (<3 months) is more likely with rhabdoid cells.[19]

Differential Diagnoses

Given the undifferentiated features of ATC, a number of other poorly differentiated tumors need to be excluded. Tumors to be considered include primary thyroid lymphoma, sarcoma (either primary or metastatic to the thyroid), squamous cell carcinoma (either primary or metastatic from nearby head/neck tumors), medullary thyroid cancer, intrathyroidal thymic carcinoma, spindle epithelial tumor with thymus-like differentiation, and other metastases (e.g., melanoma, poorly differentiated renal cell carcinoma).[14-16,20]

Immunohistochemistry stains are very helpful in identifying the origin of the thyroid malignancy.[14] Pankeratins (AE1/AE3) are positive in most ATCs; PAX-8 staining is also frequently positive,[21] as is thyroid transcription factor 1,[22] whereas thyroglobulin is never positive[9] unless there is coexisting differentiated (mostly papillary) thyroid cancer.

P53 is positive, and nuclear B-catenin may be detected. Squamous cell carcinomas are immunopositive for pankeratin, E-cadherin, and sometimes high molecular weight keratins. Lymphomas are positive for CD45 and may be positive for PAX-8, P53, and nuclear B-catenin, while medullary thyroid carcinoma is positive for calcitonin, carcinoembryonic antigen, chromogranin, and synaptophysin. Melanoma is positive for Melan-A.

Molecular Genetics

The molecular landscape of ATC is remarkably complex, with chromosomal aneuploidy, multiple gene mutations (in contrast to differentiated thyroid cancer, which has a low mutation rate), upregulated and downregulated expression of hundreds of genes, up- and downregulation of microRNAs (miRNAs), and epigenetic abnormalities.[23] Table 80.1 lists the most common mutations reported in 18 studies. *BRAF-V600E*, *RAS*, and *PIK3CA* are three oncogenic drivers commonly seen in thyroid malignancies, and the addition of *TERT-promoter* and *TP53*

TABLE 80.1 Gene Mutations in Anaplastic Thyroid Carcinoma

Mutated Gene (# Articles)	Median Prevalence (Range) %
TERT-p (13)	61 (32–82)
TP53 (18)	60.5 (25–78)
BRAF-V600E (18)	3 (6–91)
RAS (17)	24 (9–44)
CDKN2A (4)	22.5 (22–32)
PIK3CA (18)	14.5 (0–44)
PTEN (10)	11 (6–19)
NF-1 (5)	9 (9–16)

mutations (as well as other gene mutations) are responsible for the evolution of differentiated thyroid tumors to the anaplastic phenotype. Numerous other mutations have been described in one or more series, including mutations in *EIF1AX*, *NF-2*, *IDH1*, *KMT2D*, *EGF-Receptor*, *NUP93*, and other genes.[24-31] In one study, age influenced which mutations were present, with patients over 70 years old having *BRAF*, *CDKN2A*, *PIK3CA*, and *JAK2* mutations, whereas patients 50 years and younger had *NRAS*, *PTEN*, and *MYC* mutations.[32,33] Yoo et al.[33] reported that, in 27 ATC patients, *CDKN2A* loss was associated with increased disease-specific mortality, that *BRAF-mutant* tumors were associated with increased *VEGF* and *NOTCH* pathway expression and that *RAS* mutations were associated with *MAPK* pathway activity and focal adhesion. Gene fusions have also been detected in ATCs,[34] including *RET/PTC3*, *STRN-ALK*, *NUT-BRD4,* and *KIAA1549-BRAF.*[35]

Differential gene expression has been reported in multiple studies. Many hub genes are upregulated and have oncogenic properties (Table 80.2).[36-39] These genes are involved in multiple areas of cell proliferation, including mitosis, cell cycle progression, mitotic spindle checkpoint, DNA replication and repair, and telomere stability, as well as migration, invasion, epithelial-to-mesenchymal transition, and tumor angiogenesis.[36-39]

Epigenetic influences can alter gene expression by multiple mechanisms, including DNA methylation, histone modification (e.g., deacetylases; methyltransferases), chromatin remodeling, and deregulation of noncoding RNAs. The latter include both miRNAs and long noncoding RNAs (lncRNAs).[40] Multiple miRNAs are dysregulated and can affect cell function. For example, miR-205 suppresses angiogenesis, migration and invasion, and tumor growth.[41] LncRNAs also are overexpressed and participate in gene expression regulation.[42,43]

EVALUATION

Clinical and Labs

Patients should have a complete history and physical examination, as well as baseline laboratory studies. Careful attention should be paid to the head and neck examination, as this tumor is rapidly expansile and invasive. Patients frequently have impaired vocal cord function and may have direct tracheal invasion, so either mirror or fiber optic direct laryngeal examination should be performed.[44,45]

Laboratory studies should include a complete blood count with differential and platelet count, a chemistry profile to include electrolytes, blood urea nitrogen/creatinine, glucose, liver function tests, calcium and albumin to assess nutritional status, thyroid-stimulating hormone, and blood type/cross-match (if surgery is being considered).[14] Limited molecular testing should also be performed because the presence of the *BRAF-V600E* mutation could direct the choice of systemic therapy. Although rare, *ALK*, mTOR pathway, and *TRK* mutations and *RET* fusions also are targetable and could be tested.

Integrated bioinformatics analysis of hub genes and pathways in anaplastic thyroid carcinomas. *Int J Endocrinol.* 2019;2019:9651380.)

Imaging

Baseline imaging should be extensive and done quickly, to accurately stage the patient and allow for discussion of appropriate treatment options. A neck ultrasound can be done at time of presentation and provides initial information on extent of tumor within the neck, as well as the presence or absence of cervical lymphadenopathy. A contrast-enhanced computed tomography (CT) scan of the neck is also essential, as the presence of tracheal or esophageal invasion, extension into the prevertebral space, or carotid artery encasement are generally considered contraindications for extensive surgical resection. Patients should have either a positron emission tomography/CT scan from head to midthigh (preferable) or a CT of the chest/abdomen/pelvis with a bone scan, to search for systemic metastases, as well as magnetic resonance imaging (MRI) of the brain; MRI of the spine may also be indicated.[14,46-48] Thorough imaging may detect unexpected lesions and alter management in up to 50% of cases.[46]

Staging

KEY POINTS

- All anaplastic thyroid cancer are stage 4 due to its aggressive nature and risk of early metastases. However, staging is sub-categorized as IVA, B or C based on extent of disease.
- Rapid baseline clinical, lab and imaging assessment is needed, including screening for mutations involving BRAF-V600E.

Unlike differentiated thyroid malignancies, which have four stages, all ATCs are stage IV, although they are further divided into stages IVA, IVB, and IVC. In the tumor-node-metastasis (TNM) staging system, all ATC tumors were previously classified as T4 (T4a if intrathyroidal and T4b if there was gross extrathyroidal extension). In the recent American Joint Committee on Cancer 8th edition revision, the T classification was changed to be consistent with differentiated thyroid cancer, such that now ATC is classified as T1 to T4 based on the extent of the primary tumor.[49] Stage IVA is defined as a primary tumor of any size but confined to the thyroid with no lymph node involvement or distant metastases; stage IVB disease has gross extrathyroidal extension,

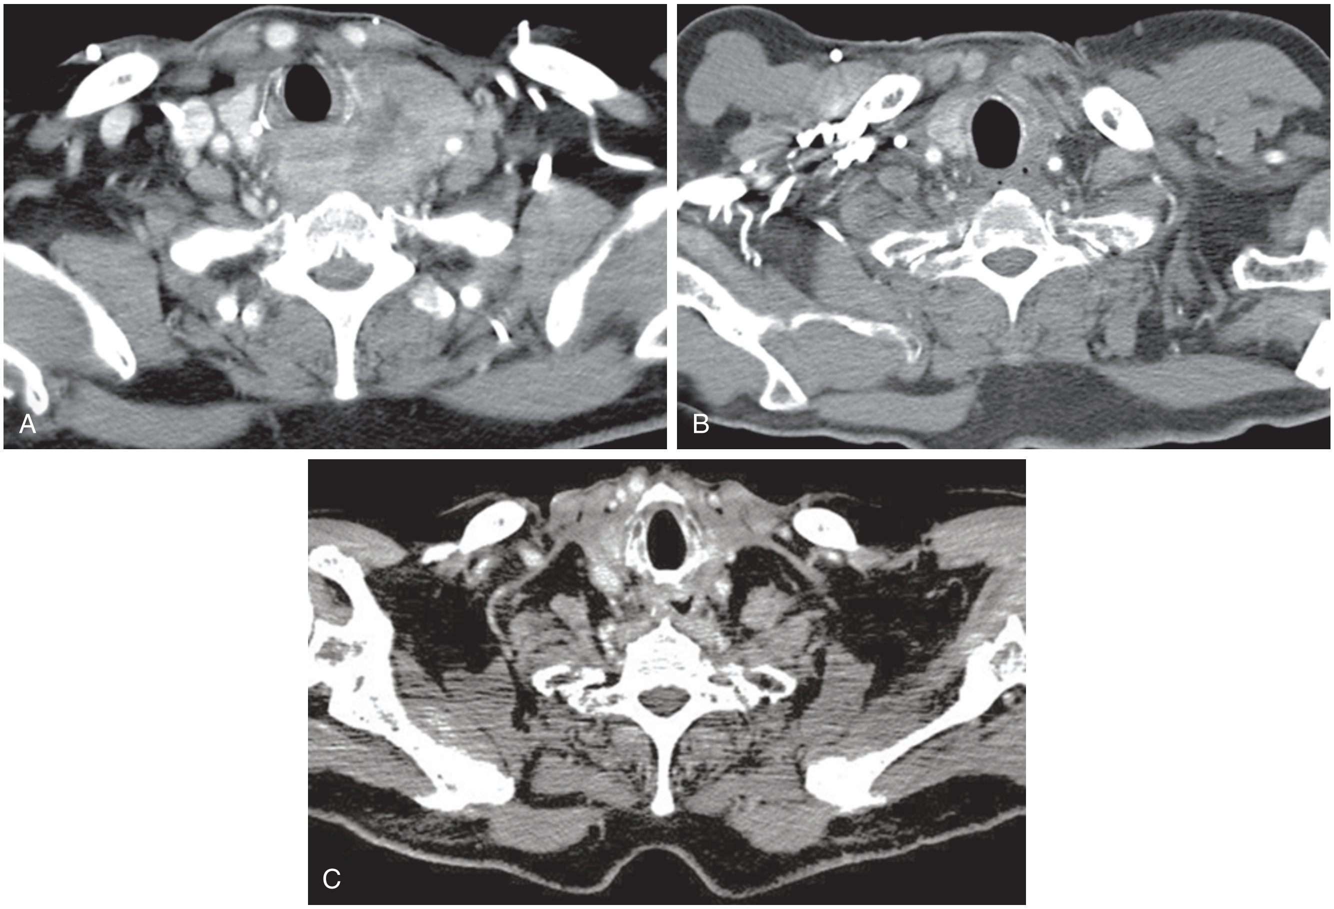

Fig. 80.2 Axial computed tomography neck imaging of a patient with stage IVB anaplastic thyroid carcinoma at diagnosis (**A**), 8 months after intensity-modulated radiation therapy and systemic chemotherapy (**B**), and 10 years later (**C**).

local regional lymph node involvement, or both, but is without distant metastases (Fig. 80.2); stage IVC disease could have a primary tumor of any size, with or without lymph nodes, but distant disease is present (Fig. 80.3). The median percentages of patients with stages IVA, B, and C disease are 10.6%, 48.3%, and 40.7%, respectively, as depicted in Table 80.3.[1,4-6,8,12,13,50-52]

ESTABLISH GOALS OF CARE

Multidisciplinary Team

Patients may present to their endocrinologist because ATC often arises after a history of longstanding goiter or prior papillary thyroid cancer. Given the rapid onset of an expanding neck mass, they may present to the emergency room with breathing difficulty and first see a surgeon. Other practitioners who should be consulted early include a radiation oncologist and a medical oncologist, and a pain/palliative care physician, social worker, psychologist or psychiatrist, and hospice physician should be strongly considered. A coordinated plan should be rapidly formulated by this team as soon as the staging is complete, and the realistic options then presented to the patient and his or her family/caregiver.[14,44,45]

It is important to establish that the patient has adequate decision-making capacity and is capable of providing informed consent. If the patient is unable to do so, then he or she should have a surrogate decision maker to guarantee adequate counseling. The risks and benefits of treatment options, which range from aggressive multimodal care to palliative care and hospice, should be disclosed. Included should be discussion of airway management,[44,45] nutrition, pain control, psychosocial issues, and advanced directives.[14,20]

KEY POINTS

- A multi-disciplinary team should be established to review all available treatment options, though also taking into account the patient's and family's wishes.
- Decision on goals of care should be determined early, though remains a fluid discussion.

PROGNOSIS

Predictors of Survival

A 2016 review determined that distant metastases carried a worse prognosis in 86% of patients enrolled in 14 studies, more extensive surgery improved survival in 78% of patients enrolled in 23 studies, radiotherapy (RT) improved survival in 74% of patients enrolled in 19 studies. In addition, tumor size was reported to influence survival in eight of 12 studies. Furthermore, age influenced survival in 56% of patients, ATC was associated with differentiated thyroid cancer in 50% of patients, and gender had no effect on survival.[53] More recently, numerous studies have shown the benefit of bimodal or trimodal therapy, high-dose RT (≥59 Gy), absence of distant metastases, younger age, smaller tumor size, and positive tumor margin.[4,6-8,11-13,20,50-52,54-67] Low poverty level and median family income have predicted survival,[55,59] as have a low lymphocyte-to-monocyte ratio[68] and leukocytosis.[62] In a review of 15 studies, surgery plus RT versus RT alone reduced risk of death (hazard ratio [HR] = 0.56), and in four reports of stage IVA patients, surgery plus RT improved survival (HR = 0.36).[54] Lai et al.[69] noted significantly shorter survival in patients whose tumors harbored a *RAS* or *PIK3CA* mutation.

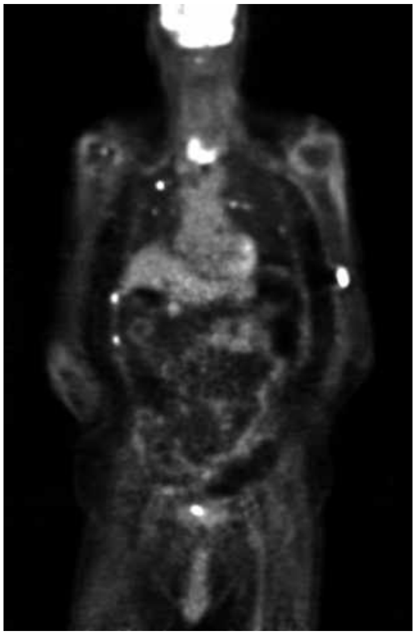

Fig. 80.3 Positron emission tomography/computed tomography imaging of patient with stage IVC anaplastic thyroid carcinoma and distant metastases to the lungs, liver, and skeleton.

TABLE 80.3 Tumor-Node-Metastasis Staging in Anaplastic Thyroid Carcinoma (16 series; *n* = 1907 patients)

Stage	Median Prevalence at Diagnosis % (Range)
IVA	10.6 (3–20)
IVB	48.3 (29–83)
IVC	40.7 (0–68)

(From references 1, 4-6, 8, 12, 13, 50-52.)

Median and Overall Survival

In a 2016 review,[53] one study reported a median survival of 33.5, 6.1, and 2.5 months in stage IVA, IVB, and IVC patients, respectively, whereas 1-year overall survival (OS) rates in these patient groups were 72.7%, 24.8%, and 8.2%, respectively. A second study included in the same review found a median survival of 9 months if tumor was confined to the thyroid, 6 months if adjacent structures were invaded, and 3 months if there was further extension or distant metastases. The 1-year survival rates for these groups were 50.0%, 27.6%, and 7.4%, respectively.

Studies performed from 2017 to 2020 have reported similar results, although recently the use of aggressive multimodal therapy, the introduction of tyrosine kinase inhibitors directed at targetable oncogenic mutations, and perhaps immunotherapy have shown some impressive improvements in response rates and duration. The median survival in these reports was 5.3 months (range: 2.0–10.6 months).[6,12,13,50,55,63,65,70-72] Only three studies provided results according to TNM stage, with median survivals in stages IVA, IVB, and IVC of 14.1, 8.2, and 5.3 months,[71] not reached (NR), 12.3, and 7.5 months,[5] and 69, 8, and 3.9 months, respectively.[65]

In a compilation of recent studies, the percentage of OS at 1 year was 27.9% (range: 0%–72%). Patient groups were heterogeneous, with many including all stages, and a variety of therapies were applied, with some studies including only patients receiving palliative care [4-6,8,12,13,51,52,58,62,65,70,71,73]; in one study grouping patients with incidental anaplastic foci, OS increased to 72%.[62] In a study of eight patients with less than 10% of their tumor being ATC (most were associated with papillary thyroid carcinoma), the 1-year OS rate was 88%, and the 2-year OS rate was 43%.[74] None of the tumors were stage IVA. In the study by Park et al.,[65] OS at 1 year was 29%, with 80% survival in stage IVA, 25% in stage IVB, and 19% in stage IVC patients. While multiple factors influenced length of survival, the most striking factor affecting duration of survival was tumor stage at time of diagnosis.

THERAPY

Treatment Strategies by Stage

Algorithms for initiating and monitoring therapy for each stage of ATC were provided by the American Thyroid Association in 2021,[14] The National Comprehensive Cancer Network also publishes treatment strategies and algorithms annually.[75] Several other recent approaches have incorporated molecular profiling to identify actionable tumor mutations for targeted therapies.[16,20] Rapid, accurate staging is critical, followed by establishing goals of care with each patient, as depicted in Fig. 80.4. These strategies have begun to show some promise in improving survival statistics, as will be reviewed in this section.

Surgery

A review of 1567 cases in the Surveillance, Epidemiology, and End Results database determined that total thyroidectomy down to complete or microscopic dissection, and when combined with other therapies, prolonged OS compared with other treatments.[55] Presumably patients undergoing extensive surgery had smaller tumors and were less likely to have systemic metastases, both of which would portend a more favorable outcome.

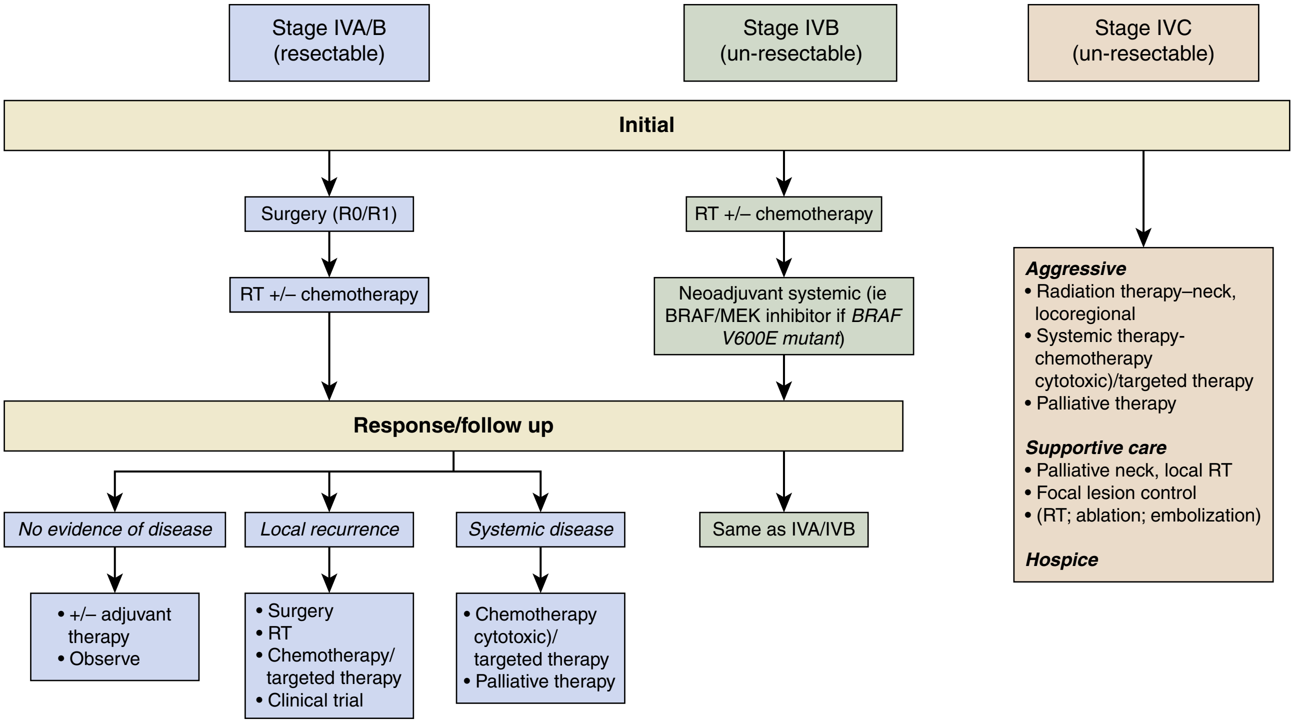
Radiation Therapy

A second United States registry, the National Cancer Database (NCDB), includes more than 79% of all new cancer cases seen at more than 1500 Commission on Cancer-accredited facilities. Using this database, Glaser et al.[56] reviewed outcomes of 3552 patients and found that patients had better survival if they received more than 59.4 Gy of radiation. A smaller subset of NCDB patients consisted of 496 who received nonpalliative surgery; 375 received adjuvant external beam radiation therapy (EBRT), of which 198 also received chemotherapy. In those patients who received EBRT after surgery versus those who did not, the OS increased from 9.1 to 12.3 months (P = .004). In those who received with EBRT with or without chemotherapy, the OS increased from 9.1 to 14.0 months.[57]

In a study of 27 patients, the median survival was 3.6 months if they received palliative RT but 11.8 months if they received definitive RT.[50] Durable locoregional control was achieved in 70% of patients, and there were five long-term survivors, whose survival ranged from 18.5 to 157 months. Park et al.[65] treated 41 patients and found that the overall median progression-free survival (PFS) increased from 2.5 to 4.5 months with RT and to 5.9 months if patients had surgery also. Median PFS was 69, 8, and 3.9 months for patients with stage IVA, IVB, and IVC, respectively. In the latter study, median OS increased from 3.9 to 7.2 months after RT and to 10.7 months if patients also underwent surgery. OS was 80%, 25%, and 19% in stages IVA, IVB, and IVC, respectively. Independent factors for survival were stage IVA, surgery, and intensity-modulated radiation therapy (better than three-dimensional conformal radiation therapy).

Multimodal Therapy

Multimodal therapy can be either bimodal (surgery + radiation, surgery + systemic, or radiation + systemic) or trimodal (surgery, radiation, and systemic therapy); systemic therapy includes cytotoxic agents, multikinase inhibitors, and immunotherapeutics.[76] For reference,



Stage IVA/B
(resectable)
Stage IVB
(un-resectable)
Stage IVC
(un-resectable)
Initial
Surgery (R0/R1)
RT +/– chemotherapy
RT +/– chemotherapy
Neoadjuvant systemic (ie BRAF/MEK inhibitor if BRAF V600E mutant)
Aggressive
• Radiation therapy–neck, locoregional
• Systemic therapy-chemotherapy cytotoxic)/targeted therapy
• Palliative therapy
Supportive care
• Palliative neck, local RT
• Focal lesion control
• (RT; ablation; embolization)
Hospice
Response/follow up
No evidence of disease
Local recurrence
Systemic disease
Same as IVA/IVB
• +/– adjuvant therapy
• Observe
• Surgery
• RT
• Chemotherapy/ targeted therapy
• Clinical trial
• Chemotherapy cytotoxic)/ targeted therapy
• Palliative therapy

Fig. 80.4 Algorithms for Anaplastic Thyroid Carcinoma Management by American Joint Committee on Cancer. *R0,* complete resection; *R1*, microscopic margins; *RT*, radiotherapy; *chemo*, chemotherapy; *NED*, no evidence of disease.

there are several reviews of the variety of drugs available and being tested,[77,78] as well as one on ABC transporters and chemoresistance.[79] In a review of 17 phase I trials (16 single-arm, one randomized), the authors concluded that the outcomes of targeted therapy were "generally disappointing" but may be improved by genetic profiling.[80]

Brignardello et al.[81] treated 55 stage IVB to stage IVC patients with "maximal debulking" (R0, R1, or R2 resections with minimal residual macroscopic disease), with prolonged survival and improved quality of life in both stage IVB and IVC patients. However, a review of 680 ATC patients in the NCDB, of whom 335 underwent surgery, recommended surgical management for intrathyroidal disease, but not necessarily in stage IVB and IVC patients.[82]

Prasongsook et al.[6] treated 48 patients (30 multimodal and 18 palliative). In the former group, 90% had surgery, average radiation was 66 Gy (range: 46–70 Gy), and cytotoxic therapies included doxorubicin, a platin, and a taxane, either as single agent or as a two-drug combination. The multimodal patients had a median PFS of 8.3 months versus 3 months in the palliative patients, and median OS was prolonged from 3.9 to 21 months. Patients with stage IVB disease had a 1-year OS of 68% with multimodal therapy versus 0% if palliative. Toxicities led to hospitalization in 60% and feeding tubes in 60%, emphasizing the importance of identifying patients able to withstand such aggressive treatment.

Rao et al.[5] reported that, in 54 patients (50% of whom were stage IVC), trimodal therapy increased median OS from 6.5 to 22.1 months versus dual therapy (EBRT/chemotherapy). A follow-up study of 479 patients from the same institution[52] found that 1-year OS was 35% from 2000 to 2013 but increased to 47% between 2014 and 2016 with the institution of a Facilitating ATC Specialized Treatment program and to 59% when targeted therapies and immunotherapeutics were introduced. Median OS increased from 7.6 to 15.7 months (HR = 0.49) with targeted/immunotherapy. In a subset of stage IVC patients, 1-year OS increased from 22% to 39% to 52%.

In another analysis of the NCDB, 858 patients were propensity score-matched to compare chemoradiotherapy (CRT) to RT.[58] The 1-year survival was 25.5% in the CRT group versus 14.3% in the RT group (HR = 0.66; $P < .001$). Corrigan et al.[51] reported that, in 28 patients, 1-year OS was 0% without EBRT but 17.9% with EBRT and increased further to 25% if surgery was also performed. They concluded that EBRT plus surgery improved survival. A study by Lee et al.[13] found that multimodal therapy prolonged median survival from 88 to 225 days.

The introduction of targeted therapy, based on molecular characterization of a patient's tumor, has recently shown promise in ATC. Monotherapy with dabrafenib in two patients showed short-term responses.[83] Most encouraging has been the dramatic improvement in OS with the combination of dabrafenib (a BRAF inhibitor) and trametinib (a MEK inhibitor) in patients with a *BRAF-V600E* mutation. Agarwal et al.[84] reported a CT imaging response for 6 months in a single patient, and a small case series of six patients (stage IVB in four; stage IVC in two) used this combination in the neoadjuvant setting, which allowed complete surgical resection and adjuvant chemoradiation.[85] OS at 1 year was 83%. Iyer et al.[86] treated ten patients with lenvatinib and 16 with dabrafenib and trametinib. The median PFS was 2.7 versus 5.2 months, and the median OS was 3.9 versus 9.3 months for lenvatinib versus dabrafenib/trametinib, respectively. Subbiah et al.[87] performed a phase II open-label trial of dabrafenib/trametinib in 16 patients; all had received prior RT and/or surgery, and six had received prior systemic therapy. While median PFS and OS were not achieved, 12-month estimates were 79% and 80%, respectively. The overall response rate was 69% (11/16). Common adverse events included fatigue (38%), pyrexia (37%), and nausea (35%). This trial led to US Food and Drug Administration approval for ATC. An earlier case report using the BRAF inhibitor vemurafenib produced a 61-week response before tumor progression.[88]

Lenvatinib is a multikinase inhibitor (targets include VEGF receptors 1–3; FGFR1–4; PDGFR-α; RET; and KIT). Iwasaki and colleagues[63] treated 16 patients with lenvatinib and 16 with palliative weekly paclitaxel. The median OS was increased from 2.0 to 4.2 months, and clinical partial responses (PRs) were achieved in five patients, but side effects were consequential, with seven developing fistulas and two exhibiting massive tumor necrosis and bleeding. In a report of 14 patients given lenvatinib (eight in the neoadjuvant setting), PRs were obtained in four patients and stable disease in nine, with a median PFS of 5.7 months and a median OS of 6.7 months.[72] Adverse events included tracheal perforation and pneumothorax/pneumomediastinum in two, as well as one fatality because of rapid tumor shrinkage. The authors concluded that there was "limited clinical benefit and there was doubtful survival benefit." The largest study of lenvatinib, from Japan, included 124 ATC patients with a median age of 73 years (range: 43–85 years); 36% were women, 53% had prior surgery, and 19% had prior systemic therapy.[10] Median OS was 3.3 months, and the 1-year survival rate was 15.6%. Responses included complete response in 3%, PR in 41%, and stable disease in 34%. Fatal adverse events were reported in 4.8%, and 8.1% had either carotid artery or venous hemorrhage, or tumor hemorrhage associated with necrosis or shrinkage.

Everolimus is an mTOR kinase inhibitor, and two small case series have been performed in ATC. In one report of seven patients, one had stable disease for 31 months and had mutations of mTOR, PIK3CA, and NF1,[89] and one patient whose tumor had PIK3CA and BRAF mutations had a "response." Both cases had TSC2 mutations. In a second study of five patients (two with stage IVB and three with stage IVC) who received everolimus, one patient had a PR for 27.9 months (this patient had activating mutations of *PIK3CA* and *BRAF*).[90]

Genetic abnormalities have directed therapy in several case reports, including one patient with a CCDC6-RET fusion who had lung and brain metastases and a greater than 19-month PR while on a trial with LOXO-292, targeting RET-fusion tumors.[91] A second patient with an *ALK* rearrangement had a 36-month response to crizotinib.[92] Rebiopsy showed a STRN-ALK fusion, and the patient then had a 16-month response to ceritinib; when cerebral progression developed, brigatinib led to a rapid PR.[93]

Finally, immunotherapeutics have been tried in animal models and in several patients. Kollipara et al.[94] had one patient with stage IVC disease and whose tumor expressed PD-L1 (3+) and PD-1 (1+); nivolumab therapy produced a complete response for 20 months. Iyer et al.[95] showed that five of 12 patients had a PR when pembrolizumab was added after progression on tyrosine kinase therapy, with median OS and PFS of 6.93 and 2.96 months, respectively.

Spalart et al.[96] reported one patient with stage IVC disease and PD-L1 immunopositivity in 60% of cells who responded to pembrolizumab for 16 months before progression. Cabanillas et al.[97] had one patient who received neoadjuvant dabrafenib and trametinib and pembrolimuzab, which permitted subsequent surgery. In another patient with stage IVC disease whose tumor was 60% positive for PD-L1, there was a dramatic response to spartalizumab (a PD-1 receptor monoclonal antibody), three patients (7%) had a complete response, and five (12%) had a PR; all responders expressed PD-L1. One-year OS was 52% in the patients expressing PD-L1.[73]

KEY POINTS

- Multi-modal therapy involving surgery (if possible to achieve complete resection), radiation and systemic therapy is the optimal approach in the management of anaplastic thyroid cancer.
- Dabrafenib and trametinib are tyrosine kinase inhibitors that specifically target BRAF-V600E mutation, and is approved for use in anaplastic thyroid cancer patients whose tumors harbor this mutation.

FUTURE DIRECTIONS

Multiple preclinical and clinical studies support the hope that additional strategies will be forthcoming. In the laboratory, newer models include patient-derived xenografts[98] and tumor organoids.[99] Additional therapeutic targets include miRNAs, lncRNAs,[42,43] histone deacetylases,[100] heat shock proteins,[101] CD47 expression,[102] to enhance tumor phagocytosis by macrophages, and CRISPR/Cas9 editing of the gene encoding the epidermal growth factor receptor.[103] Chimeric antigen receptor T cell therapy is also being tried for solid tumors, including the possibility of ATC and other refractory thyroid cancers.[104] Clearly, further progress against this deadly malignancy will benefit from novel approaches.

CONCLUSIONS

ATC is one of the most aggressive and lethal of all human malignancies. Considerable information regarding its presentation and clinical course has been accumulated over many decades, with only minimal improvement in clinical outcomes. Recently, the employment of aggressive multi/trimodal therapy with cytotoxic drugs and tyrosine kinase inhibitors, especially a BRAF/MEK inhibitor combination, has shown benefit in OS. The interrogation of patient tumors is yielding important information on the remarkable genetic and epigenetic heterogeneity of these tumors and has provided insights into targeted therapies based on an individual patient's tumor. It is hopeful that multiple agents directed at disparate oncogenic drivers will further improve patient outcomes in the not-too-distant future.

ACKNOWLEDGMENTS

Thank you to Aziza Nassar, MD and Michael Rivera, MD for providing pathologic imaging.

THYROID GLAND DEVELOPMENT, HORMONE BIOSYNTHESIS, AND ACTION

Thyroid development: Human thyroid development begins with the specification of a thyroid primordium on the median surface of the developing phyaryngeal floor, which evaginates from the endodermal epithelium at the base of the tongue around embryonic day (E) 24 and migrates caudally, initially in contact with the pharyngeal endoderm via the thyroglossal duct, which later degenerates. Throughout migration, the developing thyroid follicular cells proliferate and expand in close proximity to the aortic sac, and around E44 the ultimobranchial bodies deliver the parafollicular C cells, which fuse with the developing lateral lobes; although originally thought to derive from neural crest, C cells are now also recognized to be endodermal in origin. Once the thyroid reaches its final position anterior to the trachea, the lateral lobes enlarge, and synthesis of thyroglobulin (TG) begins. During the process of folliculogenesis, cellular functional differentiation and expression of key thyroidal genes including thyroid-stimulating hormone (TSH) receptor (*TSHR*) and thyroid peroxidase (*TPO*), followed by the sodium iodide symporter, (*SLC5A5, NIS*), prepare the fetal thyroid for thyroid hormone (TH) biosynthesis. NIS accumulation in the basolateral membrane is thought to represent the final step in thyrocyte differentiation. Fetal THs are detectable in the thyroid from approximately gestational week 11 and in fetal blood from gestational week 12.[1,2]

Thyroid transcription factors: Developing thyroid follicular cells are characterized by the combined expression of four key transcription factors from early on in development: NK2 homeobox 1 (NKX2-1, previously known as TTF1), paired box 8 (PAX8), haemopoetically expressed homeobox (HHEX), and forkhead box E1 (FOXE1, previously known as TTF-2). All interact with the promoter regions of key genes involved in thyroid differentiation (e.g., *TG, TPO,* and *NIS*), and their role in thyroid development has since been interrogated using rodent and cell culture models. NKX2-1 and PAX8 regulate expression of key genes (e.g., *TSHR, TG,* and *TPO*) involved in thyroid differentiation and play a role in murine thyroid precursor cell survival, as well as in maintenance of adult thyroid follicular cell differentiation and architecture. FOXE1 is required for differentiation and survival of the developing thyroid gland, as well as maintenance of the mature thyroid, and murine studies also support a role for FOXE1 in thyroid migration because *Foxe1-/-* mice exhibit either athyreosis or ectopy. HHEX is expressed ubiquitously throughout the foregut endoderm and is required both for thyroid morphogenesis and for maintaining the expression of PAX8 and FOXE1 in the developing murine thyroid.[1,2]

Thyroid hormone biosynthesis: Thyroid hormone biosynthesis is a complex process requiring adequate circulating iodide, appropriate thyroidal iodide handling, and sufficient TG substrate for iodination (Fig. 81.1). The sodium-iodide symporter (NIS, SLC5A5) mediates the uptake of iodide through the basolateral membrane of thyroid follicular cells (thyrocytes) by the electrogenic symport of two sodium ions for one iodide ion, down an electrochemical gradient generated by the Na^+/K^+ ATPase. Iodide efflux into the follicular lumen is facilitated by specific transporter molecules, e.g., pendrin (SLC26A4) and anoctamin-1, and iodide is oxidized in the presence of hydrogen peroxide (H_2O_2) and incorporated into tyrosyl residues on the surface of TG to form mono- and diiodotyrosyl (MIT and DIT), which are coupled to produce THs (thyroxine [T4] and triiodothyronine [T3]). TPO catalyzes the H_2O_2-dependent oxidation of I^- into I^+, the iodination of tyrosyl residues, and the coupling reactions, and H_2O_2 is predominantly synthesized by DUOX2 (an NADPH-oxidase enzyme) and its accessory protein, DUOXA2. TG-bound T3 and T4 are endocytosed back into the thyroid follicular cell then cleaved and secreted into the circulation; transporters including monocarboxylate transporter 8

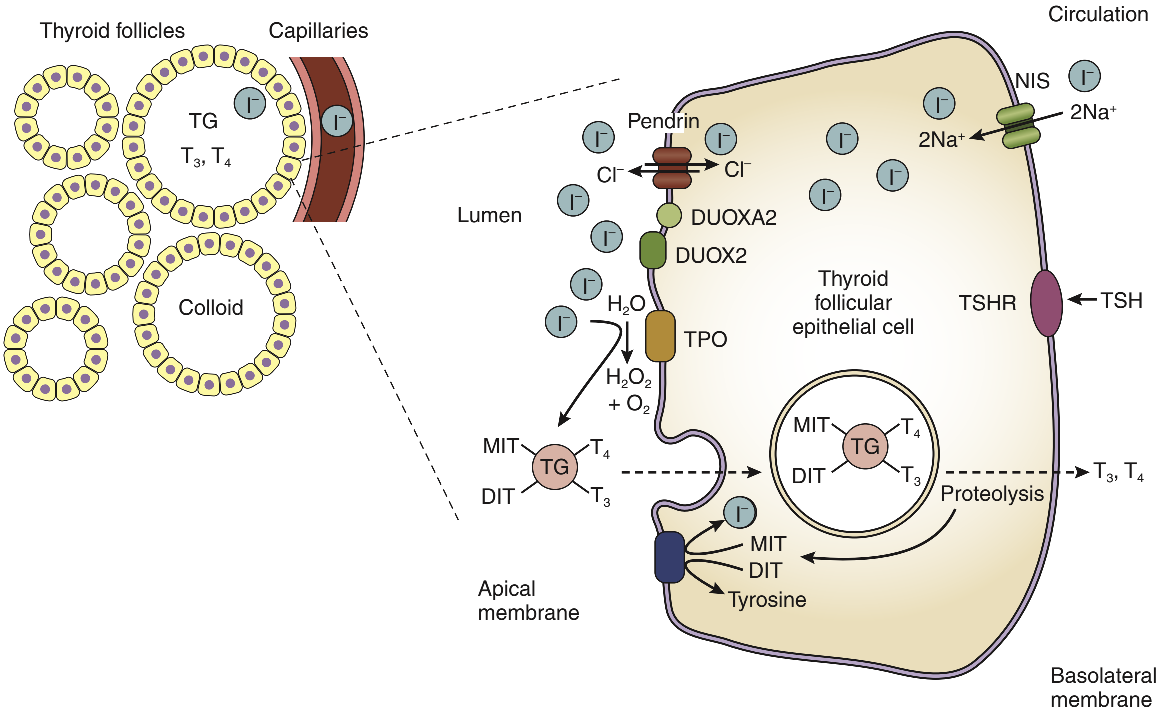

Fig. 81.1 Diagrammatic representation of a thyroid follicular epithelial cell and components of the thyroid hormone biosynthesis machinery in which mutations result in dyshormonogenic congenital hypothyroidism. (Created with Biorender.com)

(MCT8) mediate TH efflux from the thyroid gland, and iodotyrosine deiodinase (IYD) recycles unused iodide moieties.[3]

Hormone action: It is now recognized that entry of THs (T4 and T3) into cells is not a passive process. MCT8, a membrane protein, has been shown to mediate cellular TH transport, particularly in the central nervous system (CNS). Intracellularly, deiodinase enzymes (DIOs) mediate hormone metabolism, with a high-affinity type 2 enzyme (DIO2) mediating T4 to T3 conversion in the CNS, including the pituitary gland and hypothalamus, type I deiodinase (DIO1) in peripheral tissues generating T3, and type 3 deiodinase (DIO3) mediating catabolism of THs to inactive metabolites. The effects of THs on physiologic processes are mediated principally by a receptor protein, the thyroid hormone receptor (TR), belonging to the steroid/nuclear receptor superfamily of ligand-inducible transcription factors, which modulates target gene expression in different tissues (Fig. 81.2; also see Chapter 67). TR binds preferentially to regulatory DNA sequences (thyroid response elements [TREs]) in target gene promoters as a heterodimer with the retinoid X receptor (RXR), although the receptor can bind some TREs as a homodimer or monomer. In the absence of hormone, unliganded receptor homodimers/heterodimers recruit corepressors (e.g., nuclear receptor corepressor [NCoR] and silencing mediator for retinoic acid and thyroid receptors [SMRT]) to repress or "silence" gene transcription (Fig 81.3). Hormone binding results in corepressor dissociation and relief of repression, together with ligand-dependent transcriptional activation, mediated by a complex of coactivators (e.g., steroid receptor coactivator 1 [SRC-1], CREB-binding protein [CBP], and CBP-associated factor [pCAF]).[4] In humans, two highly homologous TH receptors, TRα and TRβ, are encoded by genes (*THRA*, *THRB*) on chromosomes 17 and 3, respectively. Two different proteins are generated from the TRα gene locus by alternate splicing: TRα1 is a ubiquitously expressed receptor isoform, with particular abundance in the CNS, myocardium, skeletal muscle, gastrointestinal tract, and bone; TRα2, which exhibits a modified C-terminal region such that it is unable to bind hormone, is expressed in a variety of tissues (e.g., brain and testis), and its function is not understood. The TRβ gene generates two major receptor isoforms, TRβ1 and TRβ2, which differ in their N-terminal regions: TRβ1, which is widely expressed, is the predominant isoform in liver and kidney, while TRβ2 expression is limited principally to the hypothalamus, pituitary, inner ear, and retina.[5]

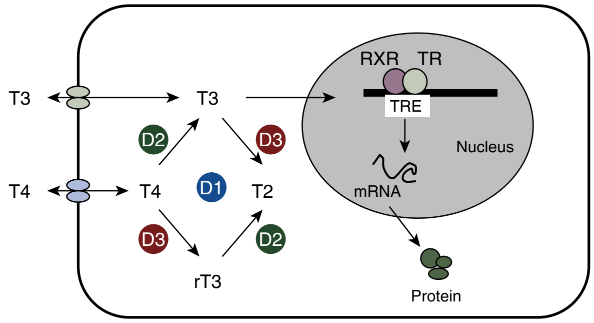

Fig. 81.2 Transport, deiodination, and nuclear action of thyroid hormones. Transporters are required for passage of triiodothyronine (T3) and thyroxine (T4) across the plasma membrane, facilitating hormone uptake, efflux, or both. Deiodinases catalyze conversion of T4 to T3 (DIO1, DIO2) or inactivation of T4 to reverse T3 and T3 to T2 (DIO3). T3 interaction with its nuclear receptor (TR), usually part of a heterodimer with retinoid X receptor, modulates target gene transcription and protein synthesis.

CONGENITAL PRIMARY HYPOTHYROIDISM

Epidemiology and Screening

Primary congenital hypothyroidism (CH) is the most common neonatal endocrine disorder, and is due either to defective thyroid

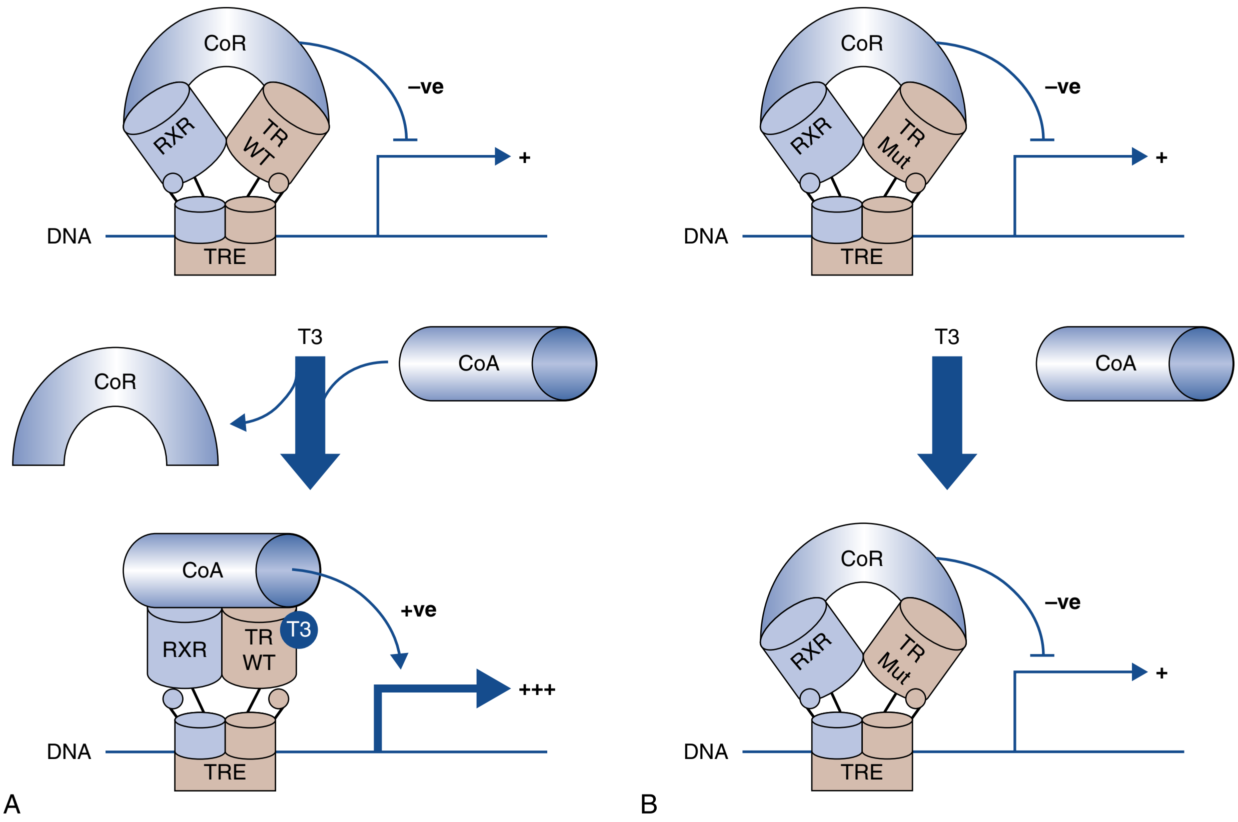

Fig. 81.3 A model for dominant-negative inhibition by mutant receptors in both resistance to thyroid hormone (RTH) β and RTHα. The left panel (**A**) depicts current understanding of wild-type thyroid hormone receptor (TR) action on target genes. The unliganded TR–retinoid X receptor heterodimer or homodimer (not shown) recruits a corepressor complex (CoR) to inhibit or silence basal gene transcription. Receptor occupancy by triiodothyronine promotes corepressor dissociation and derepression, followed by binding of coactivators (CoA), which leads to target gene activation. The right panel (**B**) shows RTH receptor mutant action. In comparison to wild-type TR, the primary defect in mutant receptors may be impaired hormone-dependent corepressor dissociation and coactivator recruitment. For the majority of receptor mutants, this functional alteration is a consequence of their reduced ability to bind ligand. However, a subset of mutants exhibit enhanced corepressor binding or delayed corepressor release or impaired coactivator recruitment *per se*, with relative preservation of hormone binding. Mutant receptor–CoR complexes compete with their wild-type counterparts for occupancy of promoter thyroid response elements (TREs), resulting in inhibition of target gene expression. In this model, DNA binding, dimerization, and corepressor interaction are functional properties that are preserved in mutant receptors and required for their dominant-negative activity.

gland development or impaired TH biosynthesis. Delayed diagnosis and treatment of CH may be devastating for childhood neurodevelopment and growth; therefore, most industrialized countries operate neonatal CH screening programs, facilitating detection of CH before signs of hypothyroidism develop. Screening strategies and biochemical diagnostic thresholds vary, worldwide and within individual nations, thereby influencing the local epidemiology of CH.

Historically, most screening programs initially measured T4 levels, with concomitant or subsequent quantitation of TSH if T4 levels were subnormal. However, increased sensitivity of TSH assays prompted a change in practice to primary TSH measurement, which improved the sensitivity of detection of primary CH. Most programs now use primary TSH-based strategies, with the remainder measuring T4 either in combination with TSH, or with secondary measurement of TSH if T4 is subnormal. In the Netherlands, a more complex algorithm includes stepwise measurement of T4 followed by thyroxine-binding globulin and TSH, enabling indirect quantitation of free T4 (FT4). There is a general consensus that detection of primary CH (for which TSH is the most sensitive measure) should be the priority for neonatal screening; however, central CH will only be detected if T4 is included in the primary screening method. Since the introduction of primary TSH-based screening strategies, TSH screening cut points have decreased, due both to improved sensitivity of TSH assays and the refinement of screening strategies to minimize false-negative results. Additionally, many screening programs now assess a second specimen in populations likely to evade detection on the initial screening test. Infants who may not generate an adequate TSH response in the first few weeks of life include those born prematurely, with very low birth weight, or with significant intercurrent neonatal illness.[6]

Primary CH has traditionally been subclassified as either thyroid dysgenesis (TD) or dyshormonogenesis (DH). TD refers to a defective thyroid gland development, most commonly thyroid ectopy, where the thyroid is situated in an ectopic site (usually sublingually) and is usually small. Twenty to thirty percent of TD cases are due to athyreosis (complete absence of the thyroid gland), and a small minority exhibit a normally located but hypoplastic thyroid. In contrast, individuals with DH exhibit inadequate TH production despite a normally located, often goitrous, thyroid gland, due to disruption of the molecular pathway for TH biosynthesis.[7]

Prior to the advent of CH newborn screening, the incidence of primary CH was estimated at 1:7000. Studies performed shortly after the introduction of newborn screening reported the actual incidence to be 1:3000 to 1:4000, likely due to the detection of individuals with delayed or more subtle clinical features of hypothyroidism. These early studies attributed approximately 75% to 85% of CH cases to TD and the remainder to DH. More recent studies have reported a doubling of the incidence of CH to approximately 1:2000. The incidence of TD has generally remained stable, and these findings are partly due to increased ascertainment of cases with a normally-located gland *in situ* (GIS CH), and milder CH, as a result of lower screening TSH diagnostic cutoffs. The proportion of cases with transient CH (neonatal hypothyroidism that resolves on retesting around 3 years of age, enabling cessation of levothyroxine treatment) has also increased. However, altered TSH cut points do not explain similar increases in incidence of CH in regions where diagnostic thresholds have remained constant, or where severe and mild GIS CH have increased.[7,8] CH incidence varies with ethnicity; therefore, altered population ethnicity may drive changes in occurrence of CH, e.g., in New Zealand, where a rise in incidence of DH was explained by an increase in percentage of Asian and Pacific Islander births.[9] The relative contributions of environmental factors such as iodine deficiency, as well as altered population demographics, including increases in preterm births, have not been ascertained.[7]

KEY POINTS

- The majority of congenital hypothyroidism (CH) is detected on neonatal screening; therefore, local screening strategies and diagnostic thresholds influence detection rate. The incidence of CH is increasing, especially that of mild or transient gland *in situ* CH; decreased thyroid-stimulating hormone screening cut points are a major contributing factor, but do not provide the sole explanation, which may be multifactorial.

Genetic Causes of Thyroid Dysgenesis

The traditional subdivision of CH into TD and DH has facilitated the identification of genetic causes of CH, with genetic mutations in TD generally involving genes with a role in thyroid development, whereas DH-associated mutations involve known components of the TH biosynthesis machinery. TD is generally considered to be a sporadic disease, with less than 5% cases attributable to a mutation in a known gene involved in thyroid differentiation, migration, and growth. In contrast, DH is usually a familial disease, with an identifiable genetic basis.

Mutations in *NKX2-1, PAX8,* and *FOXE1* are well-recognized causes of TD. Although combined expression of these transcription factors defines developing thyroid follicular cells, individually they exhibit unique extrathyroidal tissue expression patterns; therefore, mutations may be associated with characteristic, multisystem developmental defects. Mutations in GLIS3, which belongs to the GLI-similar 1-3 (GLIS1-3) subfamily of Krüppel-like zinc finger protein transcription factors, are also associated with CH. Studies in murine models have suggested that GLIS3 acts downstream of TSH and the TSHR and is essential for TSH/TSHR-mediated proliferation of thyroid follicular cells, expression of NIS and pendrin, and biosynthesis of TH. Zebrafish models have suggested that Glis3 plays a role in specification, determining the number of endodermal cells that commit to a thyroid fate. Besides transcription factor mutations, loss-of-function mutations in *TSHR* may cause TD. TSHR is a G protein-coupled receptor to which TSH binds, stimulating both thyroid growth and TH biosynthesis.[7,10,11] Genetic causes of TD are summarized in Table 81.1.

NKX2-1: The transcription factor most commonly mutated in CH is that encoded by *NKX2-1*, in which more than 100 disease-causing mutations have been reported (in the Human Gene Mutation Database [HGMD] Professional 2021.1). NKX2-1 contains two transcriptional activation domains, one on either side of the homeodomain, and mutations are detected throughout the gene, but missense mutations almost exclusively localized to the homeodomain. Haploinsufficiency is usually assumed to account for the associated phenotype, but a minority of variants exhibit dominant negative effects, which may be promoter- or tissue-specific.[12] NKX2-1 is also implicated in development of the lungs and pulmonary surfactant production, as well as the development of the ventral forebrain, in particular the basal ganglia and the hypothalamus. *NKX2-1* mutations may therefore result in cerebral and pulmonary dysfunction in addition to CH, with around half of those affected exhibiting a complete triad, so-called "brain-lung-thyroid" syndrome. More than 90% of individuals harboring *NKX2-1* mutations exhibit neurological features, typically a benign hereditary chorea manifesting in childhood that may be preceded by hypotonia, ataxia, and developmental delay. Approximately 70% exhibit hypothyroidism, which is usually mild or subclinical with normal thyroid morphology (GIS CH), although gland hypoplasia, hemiagenesis, or athyreosis are also described. Pulmonary compromise is the least common phenotype, affecting approximately 50% cases, but carries an associated mortality of up to 16% and may include severe surfactant deficiency at birth and infant respiratory distress syndrome, with recurrent infections and interstitial lung disease after the neonatal period; pulmonary involvement carries an associated mortality of up to 16%.[12,13] Rarely, pituitary abnormalities or hypothalamic dysfunction have also been reported.[14] There is poor genotype-phenotype correlation and variable expressivity and penetrance of *NKX2-1* mutations.

Key clinical considerations include the observation that *NKX2-1* mutations frequently occur *de novo*; therefore, confirmatory investigations may reassure parents that the risk to future offspring is minimal. Additionally, deletions both involving *NKX2-1* and proximal to *NKX2-1* may cause brain-lung-thyroid syndrome; therefore, exclusion of copy number variants is essential in this context.[12,13]

PAX8: PAX8 mutations are a well-recognized but uncommon cause of CH, with 43 heterozygous mutations defined as "disease-causing," as reported in HGMD. Mutations most commonly comprise substitutions affecting the DNA binding domain, although truncating mutations affecting the C-terminus and a promoter region mutation have also been reported. *PAX8* haploinsufficiency can cause CH, although some mutations exhibit dominant negative activity. Penetrance and expressivity are variable; however, truncating mutations may be associated with milder phenotypes.[15,16] Around 50% of patients harboring pathogenic *PAX8* mutations exhibit thyroid hypoplasia; however, almost a third have a normal sized, normally-located GIS CH, and a minority exhibit thyroid ectopy or athyreosis.[7] Most (but not all) affected patients exhibit CH; however, thyroid dysfunction may also be transient or subclinical and manifest in later childhood or adulthood. PAX8 is expressed in the nephrogenic mesenchyme, and although most mutations cause isolated CH, a spectrum of associated urogenital tract abnormalities have been reported, including disrupted Mullerian duct development in Mayer–Rokitansky–Kuster–Hauser syndrome.[17,18]

FOXE1: FOXE1 is a forkhead domain transcription factor that is expressed in oropharynx, esophagus, choanae, and hair follicles as well as in the developing thyroid. In contrast to *PAX8* and *NKX2-1* mutations, *FOXE1* mutations are biallelic and extremely rare, with only five definitively pathogenic missense mutations reported, all within the forkhead DNA binding domain. A highly penetrant triad of developmental abnormalities reflecting the tissue expression pattern of FOXE1 is associated with these mutations: athyreosis or severe thyroid

TABLE 81.1 A Summary of the Gene Defects and Associated Clinical Features Identified in Thyroid Dysgenesis with a Genetic Basis

Gene	M/B	Extrathyroidal Features	Biochemical Severity of Congenital Hypothyroidism	Thyroid Morphology
NKX2-1	M, often *de novo*	Neurological (BHC, developmental delay, hypotonia), respiratory (IRDS, recurrent infections)	Usually mild/subclinical ranges from euthyroid to severe	Normal GIS (majority), hypoplasia/hemiagenesis, athyreosis reported
PAX8	M	Urogenital tract malformations (rare)	Euthyroid/subclinical-moderate-severe	Typically hypoplasia (~50%), GIS (~30%), athyreosis and ectopy also reported
FOXE1	B	Cleft palate, spiky hair (universal), choanal atresia, bifid epiglottis	Severe CH	Athyreosis
GLIS3	B	Permanent neonatal diabetes, facial dysmorphia renal cystic dysplasia, hepatic fibrosis/cholestasis, glaucoma, learning difficulties, skeletal abnormalities	Severe CH, may have TSH and TG elevation despite normal FT4 on L-T4	GIS (architecture may be abnormal), athyreosis
CDCA8	M/B	Usually isolated thyroid disease, CHD in one case	Euthyroid-severe CH	Ectopy/athyreosis, in CH cases, nodules/asymmetry in euthyroid cases
JAG1	M	Alagille syndrome/ CHD, may be isolated CH	Euthyroid/ mild hypothyroidism-severe CH	Usually orthotopic hypoplasia, GIS and ectopy also reported
NTN1	M	CHD, arthogryposis	Severe CH	Ectopy
TUBB1	M/B	Macroplatelets, platelet hyperaggregation in some cases	Euthyroid to severe CH	Mainly ectopy, but hypoplasia, hemiagenesis, mild asymmetry reported in euthyroid/mild CH cases
TSHR	M/B	Nil	Compensated raised TSH-severe CH, may be difficult to normalize TSH without elevated FT4 levels	Spectrum from GIS to severe hypoplasia

M, Monoallelic; *B*, bilallelic; *GIS*, thyroid gland *in situ*; *BHC*, benign hereditary chorea; *IRDS*, infant respiratory distress syndrome; *CHD*, congenital heart disease; *L-T4*, levothyroxine; *TSH*, thyroid-stimulating hormone; *FT4*, free thyroxine; *CH*, congenital hypothyroidism; *TG*, thyroglobulin.
Only one case has been reported with *NTN1* mutations, with additional variants: 47, XYY karyotype; and atypical 22q11 deletion.

hypoplasia (one individual harboring *FOXE1* p.R102C had apparent eutopic thyroid tissue on ultrasound, but ^{131}I uptake and serum TG levels were negligible, consistent with lack of function), cleft palate, and spiky hair (Bamforth–Lazarus syndrome), with choanal atresia and bifid epiglottis also reported in some patients. *FOXE1* mutations usually impair both DNA binding and transcriptional activity, either completely (p.R102C, p.A65V, and p.F137S) or partially (p.S57N), although a gain-of-function mutation, p.R73S, has also been described, with a clinically indistinguishable phenotype.[19,20,21] Additionally, FOXE1 contains a long polyalanine tract, the length of which may influence risk of TD, with larger studies generally showing that the longer tract length (16A) may be protective for TD development.[20]

GLIS3: In recent years, biallelic *GLIS3* mutations have become a well-established, albeit very rare, cause of CH. GLIS3 contains a DNA binding domain comprising tandem repeats of five zinc fingers and a transactivation domain at the C-terminus. It has pleiotropic extrathyroidal roles, including regulation of pancreatic β cell generation, maturation, and insulin gene expression, spermatogenesis, and maintenance of normal kidney function.[10] Biallelic *GLIS3* mutations result in a variably penetrant multisystem phenotype that consistently includes permanent neonatal diabetes and CH. Additional developmental defects may include renal cystic dysplasia, congenital glaucoma, hepatic cholestasis, progressive liver fibrosis, osteopenia, and minor facial dysmorphisms. Reported mutations include exonic or larger deletions, truncating mutations resulting in loss of the GLIS3 activation domain, and missense mutations within the DNA binding domain or zinc finger motifs. Thyroid morphology in infants harboring *GLIS3* mutations ranges from apparently normal to thyroid hypoplasia or athyreosis. However, one ultrasonographically "normal" gland showed a paucity of colloid microscopically and extensive fibrosis. In some cases, TSH and TG levels remain elevated during treatment with conventional doses of levothyroxine therapy despite normalization of free T4.[22]

TSHR: TSHR mutations may be mono- or biallelic and result in a spectrum of TSH resistance, the severity of which depends both on the deleteriousness of the mutation and the number of mutated *TSHR* alleles. Complete TSH resistance (usually due to biallelic, nonfunctional *TSHR* alleles) results in orthotopic gland hypoplasia and severe CH. There may appear to be athyreosis on imaging; however, because early thyroid gland development and TG synthesis are TSH-independent, athyreosis in this context is only ever apparent, as evidenced by measurable serum TG confirming the presence of thyroid tissue. At the milder end of the spectrum (usually due to monoallelic, hypomorphic *TSHR* alleles), TSH resistance is partial, and the thyroid may be a normal size, with isolated hyperthyrotropinaemia compensating adequately for the defective TSHR, resulting in preserved TH biosynthesis and normal circulating TH levels.[7,23]

Inactivating *TSHR* mutations, especially those conferring partial TSH resistance, may be moderately common, although the incidence is influenced by the ethnicity of the population screened, with founder mutations reported, e.g., *TSHR* p.R450H in individuals from East Asia. *TSHR* mutations resulting in partial TSH resistance have been identified in up to 29% of pediatric Italian patients with nonautoimmune hyperthyrotropinaemia. There is no single "hotspot" for mutations, which may be distributed throughout the coding sequence for the receptor.[7,23]

TSHR predominantly couples to Gs and the cyclic AMP (cAMP) cascade in thyroid but signals via Gq and the phospholipase C and inositol phosphates/calcium pathway at higher TSH levels. Gq signaling is thought to stimulate thyrocyte proliferation, H_2O_2 synthesis, and apical iodide efflux, without promoting thyrocyte iodide uptake via NIS, whereas Gs/cAMP signalling may promote all of these processes. *TSHR* mutations usually result in impaired Gs/cAMP signal transduction, often due to defective membrane expression; however, mutations have been reported (e.g., p.L653V, p.R450H) that preferentially impact Gq signaling, resulting in increased radioiodine uptake due to compensatory, enhanced Gs/cAMP signaling.[24,25]

Patients with complete TSH resistance and severe CH unequivocally require levothyroxine replacement. However, whether or not individuals with partial TSH resistance and normal circulating TH concentrations require treatment remains controversial, because elevated TSH levels in these individuals may compensate for the TSHR defect. Pituitary thyrotrophs and peripheral tissues exhibit normal sensitivity to exogenous T3 administration, and the mechanisms mediating ongoing elevated TSH secretion despite normal circulating TH levels are unclear, probably reflecting a reset TSH axis setpoint in affected individuals.[26]

Some individuals may require excessive levothyroxine doses to normalize TSH levels due to such "resetting" of the hypothalamic-pituitary-thyroid axis, and the consequent supraphysiological FT4 concentrations may cause thyrotoxic symptoms. There are reports of normal growth, development, and pituitary size in untreated cases despite chronically raised TSH, and studies from Israel and Italy have investigated the need for levothyroxine treatment in this context. Cases with heterozygous *TSHR* mutations without additional risk factors for hypothyroidism generally exhibited stable TH biochemistry (isolated hyperthyrotropinaemia) during follow-up periods of up to 15 years. In the Italian study, growth and neuropsychological development were normal, irrespective of whether levothyroxine treatment was given, supporting the notion that this is a compensated state that may not require TH replacement. However, in both studies, thyroid dysfunction did progress in individuals with biallelic *TSHR* mutations, or with heterozygous mutations and additional risk factors for thyroid disease (e.g., positive autoantibodies). Therefore, although there is growing consensus that levothyroxine replacement therapy is often not indicated in partial TSH resistance, individualized treatment decisions are required, and levothyroxine should be considered in some settings.[27,28]

Additional Genes Associated with Thyroid Dysgenesis. *NKX2-5*: NKX2-5 belongs to the NK-2 family of homeodomain-containing transcription factors and plays a role in murine thyroid development, with *Nkx2-5* null mice exhibiting thyroid bud hypoplasia. This observation, together with identification of variably penetrant, heterozygous, loss-of-function *NKX2-5* mutations in patients with thyroid ectopy or athyreosis, seemed to implicate *NKX2-5* mutations in TD. However, subsequent studies have detected pathogenic mutations at higher than expected frequencies in healthy populations (p.R25C, minor allele frequency ≥1%) or in individuals with isolated congenital heart disease, mandating that, although *NKX2-5* variants may contribute to TD risk, coexisting factors/genes must also play a significant role in the pathogenesis of TD, modulating their penetrance and expressivity.[29]

JAG1: Jagged1 (JAG1) is a Notch receptor ligand expressed in thyroid that plays a role in thyroid development in zebrafish. In humans, variably penetrant, heterozygous, loss-of-function *JAG1* mutations are associated with Alagille syndrome, a rare developmental disorder with multisystem involvement. When thyroid function was assessed in a series of patients with Alagille syndrome, up to 28% exhibited mild, nonautoimmune hypothyroidism. Additionally, in a cohort of CH cases without associated Alagille syndrome, 4% harbored heterozygous loss-of-function *JAG1* mutations, substantiating the notion that JAG1 may contribute to the pathogenesis of CH, usually with orthotopic gland hypoplasia.[30]

CDCA8 (BOREALIN): CDCA8, a member of the chromosomal passenger complex with roles in the processes of chromosome segregation and cytokinesis, is a recently-identified gene associated with TD. Mono- and biallelic *CDCA8* loss-of-function mutations with variable expressivity were reported in three unrelated families in association with CH with thyroid ectopy or athyreosis, or variable thyroid structural abnormalities (asymmetry, nodules, hemiagenesis) with euthyroid biochemistry. One patient also had papillary thyroid cancer. Expression of mutant *CDCA8* in a thyroid cell line affected cellular migration and adhesion.[31]

TUBB1: TUBB1 (tubulin, beta 1 class VI) encodes a b-tubulin protein family member that heterodimerizes with a-tubulin to form cytoskeletal microtubules. *Tubb1* null mice are hypothyroid, with defective embryonic thyrocyte proliferation and migration, disrupted thyroid follicular architecture, and impaired TH secretion. Human *TUBB1* mutations have previously been associated with congenital macrothrombocytopenia; however, homozygous missense and heterozygous truncating *TUBB1* mutations were recently reported in three unrelated kindreds in association with CH, predominantly due to thyroid ectopy. These patients did not exhibit thyrombocytopenia; however, platelet size was increased, and some individuals demonstrated platelet hyperaggregation.[32]

Netrin 1 (NTN1): NTN1 is part of a family of laminin-related secreted proteins and acts as an axon guidance molecule during neural development, with additional roles in cell migration and survival and possibly in the development of pharyngeal vessels. Netrin 1-deficient zebrafish embryos exhibit defective aortic arch artery formation and abnormal thyroid morphogenesis, likely due to lack of guidance cues from dysplastic vasculature. A single patient has been reported in whom an NTN1 defect is associated with a congenital heart defect and TD (ectopy), although the contribution of *NTN1* mutations to thyroid and cardiac congenital defects in the wider population remains unclear.[33]

KEY POINTS

- Transcription factor (TF) mutations are a rare monogenic cause of thyroid dysgenesis, but may be associated with characteristic syndromic features reflecting the extrathyroidal expression of the TF involved. Genetic ascertainment in such cases may guide multidisciplinary management and permit accurate genetic counseling. Mutations in the thyroid-stimulating hormone (TSH) receptor (TSHR) may be associated with a spectrum of TSH resistance ranging from euthyroid hyperthyrotropinaemia with gland *in situ* congenital hypothyroidism (CH) to severe CH with apparent athyreosis. Isolated hyperthyrotropinaemia associated with heterozygous TSHR mutations may represent a compensated state that does not require treatment.

Genetic Causes of Dyshormonogenesis

In contrast to TD, when CH occurs due to DH, an underlying monogenic basis can be identified in the majority of cases, involving genes encoding any of the key components of the thyrocyte TH biosynthesis machinery. Genes implicated in dyshormonogenic CH include *TG, TPO, SLC26A4* (pendrin), *SLC5A5* (NIS), *DUOX2, DUOXA2, IYD,* and *SLC26A7.* Each genetic defect is associated with key biochemical and radiological hallmarks, including differences in circulating TG levels, thyroidal iodide uptake, and perchlorate discharge test results, as summarized in Table 81.2. Perchlorate discharge testing enables the discharge of accumulated intrathyroidal radioiodine to be quantified following administration of perchlorate, and provides an indirect measure of efficiency iodide organification, with greater than 90% radioiodine retained within the thyroid if organification is intact.

TABLE 81.2 A Summary of the Gene Defects Mediating Congenital Hypothyroidism with Dyshormonogenesis and Typical Associated Clinical Features

Gene	M/B	Additional Clinical Features	Congenital Hypthyroidism	Radiological Features
TG	B	Inappropriately low TG	Spectrum from euthyroidism to severe CH	GIS/goiter, iodide organification usually normal
TPO	B*		Usually severe CH, although milder phenotypes may occur, especially with monoallelic variants	GIS/goiter TIOD, rarely PIOD
DUOX2	M/B	Delayed TSH rise	Mild-moderate permanent, or transient CH	GIS/goiter PIOD
DUOXA2	M/B		Mild permanent or transient CH	GIS/goiter PIOD
Pendrin, SLC26A4	M	Sensorineural hearing loss with EVA, Mondini cochlear defect in some cases	Euthyroid if iodine replete/mild hypothyroidism	GIS/goiter PIOD
NIS, SLC5A5	M	Delayed TSH rise, delayed presentation	Spectrum from euthyroidism to severe CH	GIS/goiter, severely impaired thyroid ^{123}I/Tc uptake
IYD	M/B	Raised urinary MIT and DIT, delayed TSH rise, delayed presentation	Spectrum from euthyroidism to severe CH	Goiter, normal organification of iodide
SLC26A7	B	Delayed TSH rise, delayed presentation	Moderate-severe permanent CH	Goiter/GIS, PIOD

*Occasional monoallelic cases reported.

M, Monoallelic; *B*, bilallelic; *GIS*, thyroid gland *in situ*; *EVA*, enlarged vestibular aqueduct; *PIOD*, partial iodide organification defect; *TIOD*, total iodide organification defect; *MIT*, monoiodotyrosine; *DIT*, diiodotyrosine; *Tc*, pertechnetate; *CH*, congenital hypothyroidism; *TSH*, thyroid-stimulating hormone; *TG*, thyroglobulin.

However, genetic subtypes of DH are increasingly recognized to show a more variable and broader phenotypes than initially appreciated. Goiter may be associated with all DH-associated genetic defects, but is not universal. The mechanisms underlying variable goitrogenesis in affected individuals are poorly understood, but may include iodine status; early levothyroxine treatment may also mitigate compensatory thyroid enlargement. Rarely, fetal goiter may complicate DH, and has been reported in association with *TG, TPO, NIS,* and *DUOXA2* mutations. Circulating TG levels are elevated at diagnosis in all forms of DH except that associated with *TG* mutations.[7]

Thyroglobuin: TG is the protein on which TH biosynthesis and storage occurs through the iodination of specific tyrosine residues. CH due to *TG* mutations is a relatively common cause of DH, with an estimated frequency of at least 1:100,000 births. *TG* mutations are usually biallelic and associated thyroid dysfunction can range from severe CH to euthyroidism, with frequent occurrence of goiter. The biochemical hallmark of CH due to *TG* mutations comprises an inappropriately low serum TG level despite elevated TSH concentrations and/or goiter, or failure of exogenous TSH to stimulate a rise in serum TG. Thyroidal iodide uptake is enhanced, and iodide organification is usually preserved. T3 levels may be paradoxically normal or even mildly elevated, with low or low-normal T4, resulting in a high T3/T4 ratio; this pattern may reflect increased thyroidal type 2 iodothyronine DIO activity.[3,7] There are more than 220 CH-associated *TG* mutations, which predominantly result in TG misfolding and retention in the endoplasmic reticulum (ER), triggering ER stress.[34] Recent studies suggest that extrusion of ER-stressed, dying thyrocytes into the follicular lumen in individuals with TG mutations may release TG substrate for TH synthesis, explaining the residual TH production observed in some affected individuals.[35] Recent resolution of the full length three-dimensional structure of TG by cryo–electron microscopy, which may yield further insights into the pathogenicity of CH-associated mutations.[36]

TPO: TPO catalyzes the H_2O_2-dependent iodination of tyrosyl residues on TG to form MIT and DIT, and their subsequent coupling to form T3 and T4. *TPO* mutations frequently underlie DH in European and Pakistani cases but may occur less commonly in East Asian individuals.[37-39] Mutations are usually biallelic, and associated CH is frequently severe, often with a goitrous thyroid gland. Thyroidal iodide uptake is usually enhanced, and *TPO* mutations represent the commonest cause of total iodide organification defect (TIOD, release of >90% accumulated intrathyroidal radiodine during a perchlorate discharge test).[37,40] Heterozygous *TPO* mutations and mutations with residual catalytic function have rarely been associated with mild hypothyroidism and partial iodide organification defects (PIOD), sometimes presenting after the neonatal period. In isolated cases, heterozygous *TPO* mutations have been associated with TIOD, perhaps due to monoallelic intrathyroidal expression of TPO.[41,42] More than 100 TPO mutations have been reported that may disrupt folding and membrane insertion and/or catalytic activity, although few have undergone molecular characterization.

DUOX2 and DUOXA2: DUOX2 is a thyroidal NADPH oxidase that generates the H_2O_2 required by TPO as the final electron acceptor for both iodination of TG and the coupling reaction during TH biosynthesis. Its accessory protein DUOXA2 facilitates the delivery of DUOX2 from the ER to the plasma membrane and subsequently forms a stable complex with DUOX2 that is required for its enzymatic activity. *DUOX2* mutations occur frequently, especially in East Asian individuals,[39] and the allele frequency of some DUOX2 mutations approaches 1% in certain populations (e.g., p.Q570L in South Asians) suggesting that *DUOX2* mutations may contribute to CH even more frequently than currently appreciated. *DUOXA2* mutations are a rare cause of DH, with less than 20 mono- or biallelic loss-of-function variants reported, although some populations harbor recurrent mutations.[7,34,39,43]

Both biallelic and monoallelic *DUOX2* mutations cause CH, which is usually transient or mild permanent CH. In transient CH, the H_2O_2 synthesis defect cannot be fully compensated in the neonate, where TH biosynthesis is at its peak, resulting in neonatal hypothyroidism. However, when TH requirements decline in later childhood, other H_2O_2-synthesizing enzymes may compensate fully for the defect, resulting in resolution of hypothyroidism and enabling cessation of levothyroxine treatment. Thyroidal iodide uptake is usually normal or increased with *DUOX2* mutations, and patients exhibit a PIOD.[43,44]

Clinical data are sparse for individuals with *DUOXA2* mutations, but reported cases also demonstrate both mild permanent and transient CH with or without goiter, and PIOD.[39,43,44]

DUOX2 mutations exhibit highly variable penetrance and expressivity, and even biallelic truncating mutations, as well as heterozygous mutations, may be associated with both transient and permanent CH. It is speculated that variants in other H_2O_2-synthesizing enzymes may modulate CH severity, e.g., *DUOX1*, which encodes an additional NADPH-oxidase, is contiguous with *DUOX2* on chromosome 15, and is expressed at lower levels than DUOX2 in thyroid.[43] In support of this hypothesis, cases with likely complete DUOX isoenzyme deficiency exhibited unusually severe CH consistent with a compensatory role for DUOX1.[45] A series of UK cases harboring *DUOX2 and DUOXA2* mutations exhibited borderline neonatal bloodspot screening TSH levels followed by a delayed but significant TSH rise with subnormal venous FT4 measurements, suggesting that clinically actionable CH associated with *DUOX2 and DUOXA2* mutations could be missed on neonatal screening.[44] DUOX2 is also expressed in respiratory epithelium and throughout the gastrointestinal tract, and rare loss-of-function mutations increase risk of inflammatory bowel disease.[46]

IYD (previously known as DEHAL1): IYD is a DIO, catalyzing the deiodination of MIT and DIT residues, thereby releasing thyroidal iodide and tyrosine for further hormonogenesis. *IYD* mutations have only been formally characterized in a few families, although the description of goiter with impaired iodide recycling preceded the first molecular diagnosis by many years. Monoallelic and biallelic *IYD* mutations can both cause goitrous hypothyroidism although heterozygotes may be asymptomatic. Affected individuals exhibit rapid thyroidal uptake of iodide with a normal perchlorate discharge test and characteristically increased urinary concentrations of MIT and DIT. Hypothyroidism may manifest in childhood following a normal neonatal CH screening test result, resulting in neurodevelopmental delay if diagnosis is delayed.[40]

SLC5A5 (NIS): NIS mediates the basolateral uptake of iodide into of thyrocytes by the electrogenic symport of two sodium ions for one iodide ion, down an electrochemical gradient generated by the Na^+/K^+ ATPase. Biallelic *NIS* mutations are a rare cause of DH, and thyroid dysfunction ranges from severe CH to euthyroidism, especially if dietary iodine content is high. NIS transports both iodide and pertechnetate; therefore, mutations cause diminished or absent thyroidal radioiodine or pertechnetate uptake despite clinical or ultrasonographic evidence of a normally located, usually enlarged, thyroid gland. Tracer uptake by other NIS-expressing tissues, e.g., gastric parietal cells and salivary glands, is also reduced, and following injection of radioiodine, the ratio of salivary:plasma radioiodine is decreased in affected patients.[40] NIS-mediated CH may not manifest at the time of neonatal screening and may present with delayed TSH rise and hypothyroidism in childhood, potentially resulting in neurodevelopmental delay.[47] Because NIS mediates iodide accumulation in breast milk, prophylactic iodine supplementation of affected females may be required to prevent neonatal iodide deficiency in exclusively breastfed offspring.[48]

NIS mutations may result in loss of function due to impaired transporter function despite normal plasma membrane expression, or alternatively, mutant NIS proteins with either preserved or abrogated symporter activity may be retained intracellularly.[34,47]

SLC26A4 (*pendrin*): SLC26A4 (pendrin) is a multifunctional anion transporter that mediates both chloride-bicarbonate and chloride-iodide exchange. Biallelic mutations in pendrin cause Pendred syndrome, comprising congenital sensorineural hearing impairment with enlargement of the vestibular aqueduct, and diffuse or multinodular goiter with PIOD. These phenotypes reflect a role for pendrin in chloride-bicarbonate transport in the inner ear and in maintaining endolymphatic fluid acid-base homeostasis, as well as mediating iodine efflux at the apical membrane of the thyrocyte. A subset of cases also harbor a Mondini cochlear malformation (incomplete partition of the cochlea). Only approximately 50% patients with Pendred syndrome exhibit subclinical or overt biochemical hypothyroidism, and thyroid dysfunction or goiter are rare before puberty.[49]

SLC26A7: Biallelic loss of function mutations in *SLC26A7* represent the most recently discovered genetic cause of DH, with 19 cases now reported worldwide. Of those cases evaluated, 12 exhibit goiter, and all have permanent CH, although one case from Japan presented with hypothyroidism in childhood following a normal newborn screening TSH measurement. SLC26A7 belongs to the same family of anion transporters as pendrin and has previously been shown to function as a chloride-bicarbonate exchanger or chloride channel, mediating murine renal bicarbonate resorption and gastric acid secretion. The SlC26A7 transcript is highly expressed in human and murine thyroid, and all mutations thus far are truncating mutations, which disrupt the highly-conserved STAS domain and C-terminus of the translated protein, affecting plasma membrane localization if the truncated protein is expressed.

Individuals who have undergone further evaluation exhibit normal thyroidal uptake of radioiodine with PIOD. *Slc26a7* null mice also exhibit goitrous hypothyroidism with defective hormone biosynthesis. However, in contrast to affected humans, thyroidal radioiodine uptake is reduced in null mice with normal perchlorate discharge; additionally, null mice exhibit distal renal tubular acidosis, which was not recapitulated in affected humans.[50,51]

The role of SLC26A7 in thyroid and its location in thyroid follicular cells have not yet been conclusively ascertained. *In vitro* studies have yielded varying results, with one study reporting a role for SLC26A7 in iodide efflux, whereas another study did not observe this effect.[50,51] Future studies in thyrocytes are required to address its localization and role in thyroidal iodide metabolism, including its putative role as a direct iodide transporter. Because SLC26A7 is thought to regulate acid-base balance in the renal tubule and gastric epithelium, it has also been hypothesized that it may have an analogous function in thyroid follicular cells, where optimal ionic milieu and pH are critical for enzyme (TPO, DUOX2) and anion exchanger activities. Species differences in thyroid cell electrophysiology may then mediate divergent effects of SLC26A7 deficiency on iodide metabolism in humans and mice.

KEY POINTS

- Most individuals with dyshormonogenesis (DH) will have a mutation affecting genes involved in thyroid hormone biosynthesis, all of which cause isolated DH, except for Pendred syndrome. There is a broad spectrum of congenital hypothyroidism (CH) biochemical severity and goitrogenesis, but specific genetic mutations may be associated with specific biochemical or radiological hallmarks. Genetic testing may help predict transiency of CH or potential for delayed thyroid-stimulating hormone rise and inform genetic counseling regarding recurrence risk in future offspring.

Genetic syndromes that may include CH: CH, or hyperthyrotropinaemia, may also be a feature of multisystem involvement in other genetic syndromes, including pseudohypoparathyroidism and related disorders where TSHR signaling is impaired, without direct disruption to the *TSHR* gene, e.g., due to *GNAS* defects or monoallelic defects in *PRKAR1A* or *PDE4D*. Depending on the molecular defect, individuals may exhibit characteristic physical features (e.g., short stature, skeletal defects, obesity) ,and endocrine abnormalities including resistance to TSH and parathyroid hormone. CH or nonautoimmune hypothyroidism may also be associated with di George syndrome, for which *TBX1* is a candidate gene. Neonates and children with trisomy 21 (Down syndrome) often exhibit nonautoimmune hyperthyrotropinaemia or mild primary CH, for which the underlying mechanism is poorly understood but may involve *DYRK1A*. Say–Barber–Biesecker–Young–Simpson syndrome (*KAT6B*) and Johanson–Blizzard syndrome (*UBR1*) may also include CH, although the underlying mechanism has not been fully elucidated.[7]

Recent advances in identifying genetic determinants of CH: Historically, despite the low yield of genetic mutations identified in TD, evaluation of CH cohorts has supported a genetic basis in a larger subset of CH than is currently recognized. A large national survey of CH in France found that 2% of individuals with TD have an affected relative, which is 15-fold greater than predicted by chance alone. Moreover, thyroidal developmental abnormalities were more common in euthyroid first-degree relatives of CH cases than in controls. TD has been found to occur more frequently in consanguineous or less genetically diverse populations, and individuals with CH have an increased risk of extrathyroidal developmental malformations.[52-54]

Conversely, the greater than 90% discordance between monozygotic twins with CH, the female preponderance of thyroid ectopy, and the low frequency of causative mutations in TD seem incompatible with simple Mendelian inheritance and have been used to support the argument that TD is a sporadic disease, for which the underlying basis may include somatic mutations restricted to the thyroid or epigenetic events.[55,56] Attempts to reconcile these observations with data supporting a role for underlying genetic factors include the "two hit" hypothesis, in which a predisposing germline mutation occurs in conjunction with an additional genetic or epigenetic alteration within the thyroid gland or surrounding structures.[57] However, the only study to investigate this showed that, although ectopic thyroid exhibited differing gene expression compared with normally sited tissue, this was not due to differences in somatic gene methylation patterns. Additionally, whole-exome sequencing in lymphocyte DNA from monozygotic twins discordant for TD did not demonstrate frequent somatic mutations.[58,59] Some thyroidal genes do appear to exhibit autosomal monoallelic expression; however, there is only one confirmed case of monoallelic expression of a mutant allele (*TPO*) in association with dyshormonogenic CH.[41,60]

More recently, data from next-generation sequencing (NGS) studies have facilitated the identification of monogenic causes for CH in a greater proportion of cases. Targeted NGS of genes previously known to be implicated in TD or DH, in a hypothesis-free manner, has identified likely pathogenic variants in at least 50% individuals with GIS CH, while demonstrating significant overlap of genetic etiologies in GIS CH and TD morphological subgroups.[61] Mutations in genes characteristically associated with TD (e.g., biallelic *FOXE1* mutations) have been reported in association with GIS CH without extrathyroidal features. Conversely, *pendrin* mutations have been reported in TD, perhaps due to secondary atrophy of the thyroid due to increased oxidative stress, and *TPO* mutations have been reported in association with thyroid hypoplasia.[62,63] N-terminal DUOX2 mutations have also been reported in individuals with thyroid ectopy, raising the possibility of a role for DUOX2 and H_2O_2 production in thyroid development.[64] Crossover between classical TD-associated and DH-associated genes in the pathogenesis of both morphological subtypes of CH may partly explain the previously low mutation detection rate in phenotype-driven targeted genetic studies. Additionally, there has been ongoing discovery of novel causative genes for CH in human studies (e.g., *SLC26A7, TUBB1, CDCA8*).

A further major insight from NGS studies has been the confirmation of the role of oligogenicity in CH. In particular, NGS evaluation of 11 CH-associated genes in 177 Italian patients with GIS CH and TD identified a likely pathogenic variant in more than one gene in 25% of cases, across both morphological subgroups, that cosegregated with CH or nonautoimmune hypothyroidism in several pedigrees.[61] Similar NGS studies have implicated oligogenicity in the pathogenesis of CH across a range of ethnicities. This suggests that CH may occur due to the additive effect of multiple rare variants influencing both thyroid morphogenesis or hormonogenesis, which exert only modest effects on thyroid function when expressed in isolation. Such oligogenic inheritance may go some way towards explaining both the apparently sporadic occurrence of CH and the variable expressivity and penetrance of causal mutations.[65]

Clinical significance of genetics in congenital hypothyroidism: Molecular genetic testing, where available, may be helpful in cases of GIS CH where DH is suspected or in CH where there is a strong family history or other system involvement, and is recommended in these contexts.[6] A genetic diagnosis may assist genetic counseling and enable tailored treatment where multisystem involvement is anticipated, or where levothyroxine treatment may not be required lifelong (e.g., where hypothyroidism is likely to be transient, such as with *DUOX2/DUOXA2* mutations, and with heterozygous TSHR mutations where treatment may not be required). Additionally, for etiologies known to be associated with a delayed TSH rise, such that hypothyroidism may present in childhood despite a normal neonatal screening TSH (*NIS, DUOX2, DUOXA2, SLC26A7,* or *IYD* mutations), establishing the genetic etiology may enable prompt diagnosis in affected siblings to prevent neurodevelopmental delay. An NGS-based approach to genetic testing in CH is most likely to yield positive results.

Future studies: The advent of NGS has improved genetic diagnosis in CH, both by identifying known and novel monogenic causes in a nonhypothesis driven manner and by identifying oligogenic causes for CH. However, conclusions from NGS studies have been limited by lack of functional characterization of the rare, likely pathogenic variants identified, and future studies are required both to substantiate the functional consequences of these variants and to investigate the mechanisms by which they result in CH. Whole-exome or genome sequencing has the potential to identify further novel genetic causes of CH and to delineate novel genes involved in thyroid development or TH biosynthesis. The recent success in differentiating murine and human pluripotent stem cell-derived endodermal precursors into functional thyroid follicular structures, as well as technological advances in thyrocyte culture, present opportunities for validating the roles of such genes in the future. Additionally, the contribution of environmental factors, e.g., iodine and micronutrient status and the role of endocrine disruptors in the pathogenesis of CH, have yet to be established.

KEY POINTS

- Although monogenic causes for thyroid dysgenesis (TD) remain rare, next-generation sequencing has played a significant role in identifying genetic causes for congenital hypothyroidism (CH) by i.) highlighting a role for oligogenicity in both TD and gland *in situ* CH; ii.) confirming overlap of genetic causes across different morphological subgroups of CH; iii.) identifying novel causative genes for CH; and iv.) identifying mutations in known CH-associated genes in individuals with atypical phenotypes. Future studies are required to substantiate the functional consequences of novel variants predicted to be pathogenic *in silico* and to investigate the mechanism by which novel genes and oligogenic variants cause CH.

CLASSIFICATION OF DISORDERS OF THYROID HORMONE ACTION

Resistance to TH (RTH), first described in 1967 and characterized by elevated circulating THs (T4, T3) and nonsuppressed TSH levels

TABLE 81.3 Genetic Disorders Associated with Elevated Thyroid Hormones

Disorder	Dystranstheyretinaemic Hyperthyroxinemia*	Familial Dysalbuminaemic Hyperthyroxinaemia (FDH)	Resistance to Thyroid Hormone beta (RTHbeta)	Resistance to Thyroid Hormone alpha (RTHalpha)	Allan–Herndon–Dudley Syndrome	SBP2 Deficiency**
Gene	*TTR*	*ALB*	*THRB*	*THRA*	*MCT8*	*SBP2*
Free T4	Raised	Raised	Raised	Low-normal or low	Normal or low	Raised
Free T3	Normal or raised	Normal or raised	Raised	High-normal or raised	Raised	Normal or low
TSH	Normal	Normal	Normal (or raised)	Normal (or raised)	Normal (or raised)	Normal (or raised)
Reverse T3	Raised	Raised	Raised	Low or low-normal	Low	Raised
SHBG	Normal	Normal	Normal	Normal or raised	Raised	Raised

*Elevated thyroid hormone measurements can be intermittent.
**Low circulating selenium levels are also characteristic of this disorder.
SHBG, sex hormone-binding globulin; *T3*, triiodothyronine; *T4*, thyroxine; *TSH*, thyroid-stimulating hormone.

together with variable tissue refractoriness to hormone action, is mediated by defects in TRβ.[66] However, it is now recognized that other disorders, due to defective transport of TH into cells, intracellular metabolism of T4 to generate T3 (see Chapter 66), or hormone action via TRα, are also characterized by altered tissue sensitivity to TH. Accordingly, a consensus statement now defines RTH more broadly, to encompass all defects that can interfere with the biological action of TH secreted in normal or excessive amounts.[67]

DIFFERENTIAL DIAGNOSIS OF ELEVATED THYROXINE AND/OR TRIIODOTHYRONINE WITH NONSUPPRESSED THYROID-STIMULATING HORMONE

A number of inherited and acquired disorders are associated with differing patterns of elevated TH (T4 and/or T3) together with nonsuppressed TSH levels (see Table 9.1 in Chapter 9). The first step in making a diagnosis is to verify the validity of hormone measurements: confirmation of elevated free TH levels in two-step or equilibrium dialysis assays excludes abnormal circulating binding proteins or interfering antibodies; preservation of linearity when TSH is assayed in dilution suggests that this measurement is not artefactual. Many causes (nonthyroidal illness, psychiatric disorder, neonatal period, drugs) can be excluded by clinical context.

Genetic disorders associated with elevated TH levels and reduced sensitivity to hormone action can also be distinguished on the basis of different thyroid function test and metabolite patterns (Table 81.3).

RESISTANCE TO THYROID HORMONE β

Clinical Features

Resistance to TH due to defective TRβ (RTHβ) was first described in two siblings who were clinically euthyroid despite high circulating TH levels and who exhibited several other abnormalities, including deaf-mutism, stippled femoral epiphyses with delayed bone maturation and short stature, dysmorphic facies, winging of the scapulae, and pectus carinatum.[66] It is now clear that some of these features are unique to this kindred, in which the disorder was recessively inherited. The majority of RTHβ cases that have been subsequently described are dominantly inherited, with a highly variable clinical phenotype. Affected subjects are either asymptomatic or have nonspecific symptoms and may be noted to have a goiter, prompting thyroid function tests that suggest the diagnosis. In these individuals, classified as exhibiting generalized RTH (GRTH), the high TH levels are thought to compensate for ubiquitous tissue resistance, resulting in a euthyroid state. In contrast, a smaller number of individuals (≈15%) who share the same biochemical phenotype exhibit clinical features of thyrotoxicosis. In adults these can include weight loss, tremor, palpitations, insomnia, and heat intolerance; in children, failure to thrive, abnormal growth (either accelerated, or more commonly retarded), and hyperkinetic behavior have also been noted. When this clinical entity was first described, patients were thought to exhibit "selective" pituitary RTH (PRTH) action with preservation of normal hormonal responses in peripheral tissues.[68] However, it is now recognized that peripheral resistance (typically hepatic) to hormone action is present even in these subjects. Less commonly, hypothyroid features such as growth retardation, delayed dentition and bone age in children, or asthenia and hypercholesterolemia in adults have been observed in RTHβ and may even coexist with thyrotoxic symptoms in the same individual. Taken together, these observations suggest that the clinical features of RTHβ are variable, being governed by either resistance or retention of sensitivity to high circulating levels of free THs in different tissues.

The estimated prevalence of RTHβ is 1 in 40,000 to 50,000 live births, and the disorder can be diagnosed neonatally by screening with a combination of TSH and free T4 measurements.[69,70] Over 900 cases of RTHβ (from more than 400 families) have now been described worldwide, enabling clinical characteristics of this disorder to be defined more precisely.

Goiter. A palpable goiter has been documented in 65% of individuals, particularly adult females. The enlargement is usually diffuse, but benign multinodular change is recognized, particularly in goiters that recur following partial thyroidectomy. Development of toxic multinodular goiter on the background of RTHβ has been documented in a single case.[71] Interestingly, it has been noted that fewer children with RTHβ born to affected mothers exhibit thyroid enlargement (35%) than offspring of unaffected mothers (87%), suggesting that fetal exposure to maternal hyperthyroxinemia may protect against goiter formation.[72] The bioactivity of circulating TSH has been shown to be significantly enhanced in RTHβ, perhaps accounting for the goiter and markedly elevated serum THs observed in many cases, despite normal immunoreactive TSH levels.[73] Rarely, RTHβ cases with coexistent thyroid cancer (usually small foci of papillary carcinoma, but one metastatic) have been described[74,75]; following thyroid ablation, despite inability to fully suppress TSH levels with T4 therapy due to hormone resistance, clinical outcomes are not unfavorable.[76]

Cardiovascular system. Palpitations and resting tachycardia have been reported in approximately 75% of cases with GRTH and almost all cases of PRTH, and atrial fibrillation has been reported in 6% of patients with mutations.[72] The incidence of cardiac symptoms is notably higher in RTHβ patients than in unaffected relatives or in the general population, although still less frequent compared with patients with classic hyperthyroidism.[77] In one study, 30% of RTHβ subjects showed echocardiographic features of increased myocardial contractility and impaired diastolic relaxation, with a greater incidence of mitral valve prolapse.[72] In a prospective study of cardiovascular involvement in a large cohort of children and adults with RTHβ, resting heart rate was significantly higher, and some indices of cardiac systolic and diastolic function (e.g., stroke volume, cardiac output, maximal aortic flow velocity) were intermediate between values in normal and hyperthyroid subjects, whereas other parameters (e.g., ejection and shortening fractions of the left ventricle, systolic diameter, and left ventricle wall thickness) were not different, indicating a partially hyperthyroid response of the heart in this disorder.[77] Clinically significant mixed dyslipidaemia (total cholesterol >5 mmol/L and triglyceride >1.7 mmol/L) has been documented in 49% of an RTHβ patient cohort, together with increased hepatic and intramyocellular lipid and systemic insulin resistance, but normal carotid intima media thickness[78]; however, the hypercoagulable state associated with conventional hyperthyroidism is not present.[79]

Musculoskeletal system. Stippled epiphyses and winged scapulae were noted in the original RTHβ kindred, but have not been observed in other cases, such that these features may represent a specific manifestation of the known gene deletion (*THRB*) or an unrelated genetic abnormality in this consanguineous kindred.[66] In contrast, growth retardation and delayed skeletal maturation are more common in childhood RTHβ patients, with height below the fifth percentile in 18% and delayed bone age (>2 standard deviations) in 29%,[72] with no significant differences between GRTH and PRTH cases. However, despite these abnormalities, final adult height is often not affected.[80]

Bearing in mind the known adverse effects of untreated hyperthyroidism on bone mineralization, we conducted a cross-sectional survey of approximately 80 adult subjects with RTHβ and observed a reduction in bone mineral density in the femoral neck (mean Z score –0.71) and lumbar spine (mean Z score –0.73) but with normal markers of bone turnover (Moran & Chatterjee, unpublished observations).

Energy intake and expenditure. We have documented raised resting energy expenditure (REE) (metabolic rate), mediated by uncoupling of oxidative phosphorylation and mitochondrial ATP synthesis, in skeletal muscle of RTHβ patients. Energy intake is also increased, particularly in childhood.[81] Indeed, an imbalance between such hyperphagia and increased total energy expenditure (reflecting raised REE and increased physical activity due to attention deficit hyperactivity disorder [ADHD]; see later) may account for the abnormally low body mass index seen in approximately one third of children.

Central nervous system. Two studies have documented neuropsychologic abnormalities in RTHβ. First, a history of ADHD in childhood was elicited more frequently in patients with RTHβ (75%) compared with their unaffected relatives (15%).[82] A second study showed that both children and adults with RTHβ exhibited problems with language development, manifested by poor reading skills and problems with articulation, including speech delay and stuttering.[83] However, frank mental retardation (intelligence quotient [IQ] <60) is relatively uncommon (3%), although 30% of patients show mild learning disability (IQ < 85), probably due to CNS resistance to TH action.[84] A direct comparison of individuals with ADHD and RTHβ versus ADHD alone indicates an association with lower nonverbal intelligence and academic achievement in the former group.[85] However, two different surveys of unselected children with ADHD failed to detect any cases of RTHβ by biochemical screening, suggesting that this thyroid disorder is unlikely to be a common cause of hyperactivity.[86] Although magnetic resonance imaging shows that anomalies of the sylvian fissure or Heschl's gyri are more frequent in RTHβ, these features do not correlate with ADHD.[87]

Hearing and vision. Significant hearing loss has been documented in 21% of RTHβ cases, similar to the prevalence reported in CH.[72] In the majority, audiometric tests indicated a conductive defect, probably related to the increased incidence of recurrent ear infections in childhood RTH (67% in RTH vs. 28% in normal controls). Abnormal otoacoustic emissions, consistent with cochlear dysfunction, have also been documented in those with hearing deficit,[72,88] and cochlear expression of TRβ has been shown.[89] The single kindred with deafmutism and recessively inherited RTHβ harbored a complete deletion of the TRβ gene.[66] Overtly abnormal color vision has only been reported in the rare human kindred with recessively inherited RTHβ and a complete *TRβ* gene deletion,[66] or a case with compound heterozygous *TRβ* mutations.[90] Impaired color perception, together with reduced cone and rod function, have been documented in heterozygous RTHβ patients.[91] Together with knowledge that TRβ knockout mice are deaf[92] and that TRb2 null mice have loss of M-cone photoreceptors and abnormal color vision,[93] these observations underscore the important role of TRβ in the audiovisual system.

Other associated disorders. Coexistence of RTHβ with autoimmune thyroid disease has been reported[94]; thyroid autoantibodies are more prevalent in RTHβ subjects than in unaffected relatives, suggesting a possible pathogenic link between these disorders.[95] Coexistence of Pendred syndrome[96] or TD[97] and RTHβ has been documented. Pituitary enlargement, as a consequence of impaired negative feedback regulation of TSH secretion, is another potential association with RTHβ. While pituitary hyperplasia has been reported in a single case, it occurred in the context of massively elevated TSH levels with suboptimal T4 replacement therapy following inappropriate thyroid ablation, and regressed once TSH levels normalized.[98] Only a few cases of RTHβ associated with pituitary adenomas have been described,[99,100] suggesting that pituitary hyperplasia or adenoma formation are not common clinical sequelae in RTHβ, provided that the altered set point of the hypothalamic-pituitary-thyroid axis is not perturbed. A greater frequency of recurrent upper respiratory tract and pulmonary infections has been reported in RTHβ, and affected individuals have reduced serum immunoglobulin levels.[72] A retrospective study of a large Azorean kindred has shown a higher rate of miscarriage in mothers with RTHβ, with fewer unaffected offspring than expected being born and exhibiting lower birth weight and transient suppression of TSH levels neonatally, suggesting that intrauterine exposure to high maternal TH levels does have adverse fetal effects.[101]

Differential Diagnosis

Differentiation of RTHβ, particularly the form associated with hyperthyroid features, from a TSH-secreting pituitary tumor can be difficult. Similar abnormalities in thyroid function tests in first-degree relatives strongly suggest RTHβ, together with normal pituitary imaging and serum α-glycoprotein subunit levels. Other factors that are helpful in making this differential diagnosis, such as dynamic testing and clinical/biochemical features, are discussed in greater detail in Chapter 9.

The development of Graves disease in RTHβ is suggested by atypical features such as ophthalmopathy, severe thyrotoxic symptoms, and a further rise in THs leading to a subnormal or suppressed TSH. Following antithyroid drug treatment, TSH levels become elevated despite normalization of THs. Similarly, requirement of T4 replacement in supraphysiologic dosage to normalize TSH in autoimmune hypothyroidism and associated with elevated FT4 and free T3 (FT3) levels suggests coexistent RTHβ.

TABLE 81.4 Tissue Indices of Thyroid Hormone Action

Pituitary:	Thyroid-stimulating hormone (TSH)
General:	Basal metabolic rate (BMR)
Hepatic:	Sex hormone-binding globulin (SHBG), ferritin, cholesterol
Muscle:	Creatine kinase, ankle jerk relaxation time
Bone:	Height, bone age, bone density, osteocalcin, alkaline phosphatase, pyridinium crosslinks, type 1 collagen telopeptide
Cardiac:	Sleeping pulse rate, systolic time interval, diastolic isovolumic relaxation time
Hematologic:	Soluble interleukin-2 receptor (sIL-2R)
Lung:	Angiotensin-converting enzyme (ACE)

In addition to clinical features, the measurement of various tissue markers of TH action has been suggested to be a useful method for evaluating the differing responses of various target organs and tissues to elevated circulating THs (Table 81.3). These measurements are most useful in assessing the tissue effects of marked TH excess (as typically found in overt thyrotoxicosis) but may be less discriminatory in borderline hyperthyroidism or in hypothyroidism. To improve the sensitivity and specificity of these parameters, it has been suggested that individuals with RTHβ are assessed by measuring tissue responses dynamically, following the administration of graded supraphysiologic doses of T3 (50, 100, and 200 µg/day, each given for a period of 3 days), with comparison of any change in indices from baseline values to those observed in normal subjects.[102]

KEY POINTS

- Thyroid hormone receptor (TR) β2 plays a key role in negative feedback regulation within the hypothalamic-pituitary-thyroid axis, as well as the audiovisual system, likely accounting for the biochemical pattern of elevated thyroid hormones, with nonsuppressed thyroid-stimulating hormone, that defines resistance to thyroid hormone β, together with auditory and visual abnormalities. Predominance of TRβ1 in the liver mediates dyslipidemia and normal hepatic markers of thyroid hormone action. Conversely, hyperthyroid features of the disorder are due to actions of high circulating thyroid hormones in tissues expressing normal TRα1.

Molecular Genetics

TRβ RTH. Following the cloning of *TRα* and *TRβ*, RTHβ was shown to be tightly linked to the *TRβ* gene locus in a single family.[103] This prompted analysis of the *TRβ* gene in other cases, and a large number of receptor defects have since been associated with this disorder. Eighty percent of RTH is familial, dominantly inherited, and associated with heterozygous mutations in the TRβ gene[84,104-106]; *de novo* receptor mutations occur in the remaining 20% of sporadic cases. Over 218 different defects, including point mutations, in-frame deletions, and frame-shift insertions, have been documented to date, which localize to three mutation clusters within the ligand-binding domain of the receptor (Fig. 81.4). Within each cluster, some codon changes (e.g., R243W, R338W, R438H), representing transitions in mutation-prone CpG dinucleotides, occur more frequently and are overrepresented.[107]

Based on the supposition that PRTH was associated with selective pituitary resistance, it had been hypothesized that this disorder may be associated with defects in DIO2 or the TRβ2 isoform. However, a number of reports have documented *TRβ* mutations in PRTH.[105,108] Receptor mutations found in individuals with PRTH have also been associated with GRTH in unrelated kindreds. Furthermore, even within a single family the same receptor mutation can be associated with abnormal thyroid function and thyrotoxic features consistent with PRTH in some individuals, but similar biochemical abnormalities and a lack of symptoms indicative of GRTH in other members. Overall, these findings indicate that GRTH and PRTH represent the phenotypic spectrum associated with a single genetic entity.

Non-TRβ RTH. In a small but significant number of cases (approximately 10%–15%), clear-cut biochemical evidence of RTHβ is not associated with a mutation in the coding region of *TRβ*—giving rise to the term non-TRβ RTH. However, one explanation for this is somatic mosaicism, with occurrence of a *TRβ* mutation whose expression is selective, being detectable in some tissues but not peripheral blood leukocyte DNA.[109] Alternatively, documentation of sporadic or familial with elevated TH and resistance to T3 administration in whom genetic studies have excluded THRB defects[110,111] raises the possibility that mutations in other factors that are required for TH-dependent gene transcription (e.g., RXR, corepressors, coactivators) could manifest as RTHβ, although no defects in these genes have been identified as yet.

Properties of Mutant Receptors. Consonant with their location in the hormone-binding domain, the majority of receptor mutants identified in RTHβ exhibit moderate or markedly reduced T3 binding; consequently, their ability to activate or repress target gene expression is impaired.[112,113] A subset of RTHβ mutations associated with markedly abnormal thyroid function *in vivo* and altered transcriptional function *in vitro*, but little impairment in ligand binding, have been described. Such natural mutations involve residues that mediate receptor interaction with transcriptional coactivators.[106,114] In the first RTHβ family described,[66] with the recessively inherited form of the disorder, the two affected siblings were found to be homozygous for a complete deletion of both alleles of the *TRβ* gene.[115] Importantly, the obligate heterozygotes in this family, harboring a deletion of one *TRβ* allele, were completely normal, with no evidence of thyroid dysfunction. This suggested that simple deficiency of functional beta receptor, as a consequence of the single deleted *TRβ* allele, was insufficient to mediate the hormone resistance phenotype. This led to the hypothesis that, in dominantly inherited RTHβ, heterozygous mutant receptors were not simply functionally impaired, but also capable of inhibiting the action of wild-type receptor. Studies confirmed that, when coexpressed, the mutant proteins are able to inhibit the function of their wild-type counterparts in a dominant-negative manner.[116,117] Further clinical and genetic evidence supporting this notion has been provided by rare examples of RTHβ. In the first, a childhood case, severe resistance with marked developmental delay and growth retardation associated with cardiac hyperthyroidism was ultimately fatal due to heart failure following septicemia; this individual was homozygous for a mutation (Δ337T) in both alleles of the *TRβ* gene.[118] Several additional cases with a severe clinical phenotype and either homozygous or hemizygous for *TRβ* defects have been described.[119] Presumably, the extreme phenotype observed in such cases reflected not only the absence of normally functioning TRβ, but the added dominant-negative inhibitory effect of mutant β receptors.

Functional studies of mutant receptors indicate that, although they are transcriptionally impaired and dominant-negative inhibitors, their ability to bind DNA and form heterodimers with RXR is preserved.[112,113] Conversely, it has been shown that the introduction of additional artificial mutations that abolish DNA binding or heterodimer formation abrogates the dominant-negative activity of mutant receptors *in vitro*.[113,120,121] Mice heterozygous for a *TRβ* mutation that results in a lack of DNA binding do not exhibit RTH.[122] It has also been suggested that the ability of mutant receptors in RTHβ to repress

Fig. 81.4 **A,** A schematic representation of the domains of TRβ showing that, with two exceptions (Q374K, R383C/H), resistance to thyroid hormone (RTH) β receptor mutations localize to three clusters within the ligand-binding domain (LBD). The receptor defects described hitherto include different missense substitutions at each codon, in-frame codon deletions (Δ), premature termination codons (X), and frame-shift mutations (*). The mutations shown include those listed in a public database (Human Gene Mutation Database) together with our unpublished data. No RTH receptor mutations have been described in the zinc-finger DNA-binding domain (DBD) or its carboxy-terminal extension (CTE), which together mediate interaction with DNA, or regions in the LBD that are important for corepressor binding or dimerization with retinoid X receptor. **B,** The crystal structure of the thyroid hormone receptor β LBD (Protein Data Bank accession no. 1BSX) composed of 12 α-helices (grey) is shown, with the location of missense mutations associated with RTH (Cluster I yellow, Cluster II green, Cluster III red, R383 and Q374 cyan) superimposed. As predicted from their functional properties, the majority of mutations involve residues which surround the ligand (triiodothyronine cyan) binding cavity. (See Color Plate.)

or "silence" basal gene transcription is likely to be an important factor contributing to their dominant-negative potency. Non-T3-binding receptor mutants exhibit constitutive silencing function, particularly when bound to DNA as homodimers, which cannot be relieved by ligand; conversely, RTHβ mutants with impaired homodimerization properties are weaker dominant-negative inhibitors.[123] With the identification of corepressors, these observations have been extended to show that some RTHβ mutants either bind corepressor more avidly when unliganded or fail to dissociate fully from corepressor upon T3 binding.[124] Furthermore, artificial mutations that abolish corepressor binding abrogate the dominant-negative activity of RTHβ receptor mutants.[124] An unusual RTHβ receptor mutant (R383H) exhibits both delayed T3-dependent corepressor release and impaired hormone-dependent negative transcriptional regulation.[125] Given the pivotal role of negatively regulated target genes in the pathogenesis of RTH, aberrant corepressor recruitment or release may well prove to be the critical receptor abnormality in this disorder.

Together, these observations allow a model to be constructed (Fig. 81.3) in which occupancy of target gene binding sites by mutant receptor–corepressor complexes mediates dominant-negative inhibition by RTH mutants. Mapping of the three clusters of RTHβ receptor mutations identified hitherto onto the crystal structure of the ligand-binding domain of TRβ[126] provides insights into structure-function relationships in TR (Fig. 81.4). As expected from their impaired ligand-binding properties, most TRβ mutations are located around the hormone-binding cavity; in contrast, receptor regions mediating DNA binding, dimerization and corepressor interaction are devoid of naturally occurring mutations, possibly because they lack dominant-negative activity and are therefore biochemically and clinically silent.

This model also has important implications in interpreting the significance of *THRB* variants identified by NGS. Specifically, *in silico* prediction algorithms may not always reliably predict the pathogenicity of variants not previously reported to be associated with RTHβ.[127] The functional significance of new *THRB* variants is best determined by assessing transcriptional function and dominant-negative activity of TRβ mutants *in vitro* or by showing that the mutant genotype cosegregates with abnormal thyroid function in families.[128]

Pathogenesis of Variable Resistance. Genetic and functional evidence suggests that the ability to exert a dominant-negative effect on target genes within the hypothalamic-pituitary-thyroid axis is a fundamental property of RTHβ receptor mutants, generating the abnormal thyroid function characteristic of the disorder. Indeed, studies indicate that, for a subset of RTHβ mutants, there is a correlation between their functional impairment *in vitro* and the degree of hormone resistance *in vivo*, quantified by the magnitude of elevation in serum FT4 or cholesterol in patients.[78,129] On this background, the heterogeneous clinical phenotype may be due to differing degrees of peripheral resistance in different individuals, as well as variable resistance in different tissues within a single subject. A number of factors may contribute to such variable tissue resistance.

One important contributory element may be the differing tissue distributions of receptor isoforms. As the hypothalamus, pituitary, and liver express predominantly TRβ2 and TRβ1 receptors, respectively, and TRα1 is the major species detected in myocardium, mutations in the *TRβ* gene are likely to be associated with pituitary and liver resistance, as exemplified by nonsuppressed TSH levels and normal sex hormone-binding globulin seen in patients, whereas the tachycardia and cardiac hyperthyroidism in some cases may represent retention of myocardial sensitivity to high circulating THs acting via a normal alpha receptor. Another factor that may influence the degree of tissue resistance is the relative expression of mutant versus wild-type *TRβ* alleles. While one study has suggested that both alleles are equally expressed,[130] another showed marked differences in the relative levels of wild-type and mutant receptor messenger RNA in skin fibroblasts from two RTHβ cases.[131] In one of these individuals, a temporal variation in expression of the mutant allele in fibroblasts appeared to correlate with the degree of skeletal tissue resistance. The dominant-negative inhibitory potency of mutant receptors has been shown to differ depending on target gene promoter context[113,132] and is a further variable that may influence the degree of resistance. Finally, non-*TRβ*-related factors might influence the phenotype. For example, a deleterious R316H mutation was associated with normal TH levels in some members of one kindred[133] but clearly abnormal thyroid function in an unrelated family,[105] suggesting that other genetic variables can modulate the effect of receptor mutations.

While the absence or presence of overt thyrotoxic features allows patients to be classified as either GRTH or PRTH—a clinical definition that will probably remain useful as a guide to the most appropriate form of treatment—studies indicate that there is some overlap of features between the two forms of the disorder. For example, there are no significant differences in age, sex ratio, frequency of goiter, thyroid function, or clinical features between patients with GRTH or PRTH.[134] Importantly, features such as tachycardia, hyperkinetic behavior, and emotional disturbance have been documented in individuals with GRTH.[134] Conversely, serum sex hormone-binding globulin, a hepatic index of TH action, is almost invariably normal in patients with PRTH, suggesting that hormone resistance is not solely confined to the hypothalamic-pituitary-thyroid axis in this group of patients.[135]

Attempts to correlate the phenotype of RTHβ with the nature of the underlying *TRβ* mutation have been confounded by imprecision of criteria used to classify cases as GRTH and PRTH, spontaneous temporal variation in hyperthyroid features in some RTHβ patients,[134] and the relatively small number of patients with any given mutation that have been identified hitherto. Nevertheless, some interesting correlations have emerged from the published literature. The first patient reported to have PRTH[68] was found to harbor an R338W receptor mutation,[108] and the same phenotype has been described in the majority of individuals with this or similar substitutions at this codon.[108] Interestingly, when tested *in vitro*, this mutant exhibits dominant-negative activity with the negatively regulated pituitary TSHα subunit gene promoter but is a relatively poor inhibitor of wild-type receptor action in other promoter contexts.[113] Furthermore, when introduced into other RTH receptor mutant backgrounds, this mutation weakens their dominant-negative potency on positively regulated reporter genes.[136] More recently, it has been suggested that a noncoding polymorphism in the *TRb2* promoter of the mutant allele amplifies pituitary expression of R338W in this patient, further augmenting pituitary dominant-negative activity.[137] A patient with the R383H receptor defect, which is impaired mainly in regulation of thryotropin-releasing hormone and *TSH* genes, exhibited predominant central resistance following T3 administration,[138] and the R429Q mutation, with similar functional properties, may also occur more frequently in association with PRTH. Some receptor mutants (R338W or L, V349M, R429Q, I431T) associated with PRTH are either more deleterious[139] or exert a greater dominant-negative inhibitory effect in a TRβ2 than TRβ1 context.[140] A receptor mutation that selectively fails to bind NCoR but not SMRT is associated with PRTH.[141]

KEY POINTS

- The disorder is usually mediated by heterozygous, loss-of-function thyroid hormone receptor (TR) β mutants that inhibit the function of their wild-type receptor counterparts in a dominant-negative manner. Homozygous, but not heterozygous, *TRβ* haploinsufficency causes resistance to thyroid hormone (RTH) β; a severe phenotype is associated compound heterozygosity or homozygosity for dominant-negative *TRβ* mutations. The genetic basis of 10%–15% of RTH cases that are devoid of THRB mutations remains to be elucidated.
- Factors contributing to variable hormone resistance include differing dominant-negative activity of THRB mutants in different target gene, TRβ2 vs. TRβ1 isoform, or tissue contexts.

Management

The management of RTHβ is difficult, because variable resistance makes it difficult to maintain euthyroidism in all tissues. However, the majority of patients do not require specific treatment, and in general the presence or absence of hyperthyroid features is a useful guide to the need for therapy. In most individuals, the receptor defect is compensated by high circulating TH levels, leading to a euthyroid state, which is not associated with abnormalities other than a small goiter. Attempts to treat the biochemical abnormality with surgery or radioiodine are usually unsuccessful, with recrudescence of the goiter (often nodular in nature) and disruption of the thyroid axis.[84] Certain circumstances, such as hypercholesterolemia in adults or developmental delay and growth retardation in young children, may warrant the administration of supraphysiologic doses of levothyroxine to overcome a higher degree of resistance in certain tissues. Although successful in some cases,[84] such therapy needs careful monitoring of indices of TH action (e.g., sex hormone-binding globulin, heart rate, basal metabolic rate, bone markers) to avoid the adverse cardiac effects or excess catabolism associated with T4 overtreatment. Inappropriate thyroid ablation also renders the RTHβ patient hypothyroid, with elevated TSH levels and risk of thyrotroph hyperplasia,[98] and is another context in which supraphysiologic T4 replacement is indicated. Alternate day administration of liothyronine in supraphysiologic dosage led to significant regression of goiter without inducing thyrotoxic symptoms in one case.[142]

In contrast, a general reduction in TH levels may be of benefit in the management of patients with thyrotoxic symptoms. However, the administration of conventional antithyroid drugs usually causes a further rise in serum TSH levels, which stimulates thyroid enlargement and may also induce thyrotroph hyperplasia, with a theoretical risk of developing autonomous neoplasms at either site. Accordingly, agents that inhibit pituitary TSH secretion, yet are relatively devoid of peripheral thyromimetic effects, are administered to reduce TH levels. The most widely used example is the TH analog 3,5,3'-triiodothyroacetic acid (TRIAC), which has been shown to be beneficial in both childhood and adult cases.[143-146] This compound has a number of interesting properties that make it an attractive therapeutic option in RTHβ: (1) it exerts predominantly pituitary and hepatic thyromimetic effects *in vivo*,[147] target tissues that are relatively refractory to THs in RTHβ; (2) it has greater affinity, potency, and activity than T3 for TRβ[148]; (3) it exhibits a higher affinity for TRβ than TRα *in vitro*[149]; and (4) it can activate some TRβ mutants *in vitro*.[149] A daily dose of 1.4 to 2.8 mg is generally used, and twice daily administration enhances TSH inhibition.[150] TRIAC has been successfully used in pregnancy to control maternal thyrotoxic symptoms, but may have induced fetal goiter.[151] With known spontaneous variation in thyrotoxic symptoms in RTH, periodic cessation of TRIAC therapy and reevaluation of patient clinical status is advisable. Treatment with TRIAC is not always effective,[152] and dextrothyroxine is another agent that has been shown to be useful in some cases.[153,154] However, past experience indicates that TSH secretion escapes from the inhibitory effects of bromocriptine,[143,155] as well as somatostatin analog.[156] Use of antithyroid drugs in combination with TRIAC was beneficial in homozygous RTHβ associated with hyperthyroid cardiomyopathy.[157] Thyroid ablation followed by subphysiologic T4 replacement may also be warranted in cases of RTHβ associated with life-threatening thyrotoxic cardiac failure.

The treatment of thyrotoxic features (e.g., failure to thrive) in childhood RTHβ also requires careful monitoring to ensure that any reduction in TH levels is not associated with growth retardation or adverse neurologic sequelae. Indeed, control of cardiac and sympathomimetic manifestations with β-blockade may be the safest course in this context. Counterintuitively, one study reported that liothyronine therapy improved hyperactivity in nine children with ADHD and RTH, including three individuals who were unresponsive to methylphenidate, and it is conceivable that lower circulating T4 levels may have mediated this.[158] Supporting this notion, TRIAC therapy ameliorated ADHD in one childhood case.[159]

Lipid-lowering therapy may be warranted in patients with hypercholesterolaemia and other cardiac risk factors. Lifestyle changes (e.g., increased physical activity, weight loss) can be recommended in individuals with features of metabolic syndrome (central adiposity, hypertriglyceridaemia, low high-density lipoprotein cholesterol, insulin resistance). Resmetirom, a TRβ-selective agonist that lowers hepatic fat, circulating low-density lipoprotein cholesterol, and triglyceride levels in patients with nonalcoholic steatohepatitis,[160] may represent future rational therapy in patients with mixed dyslipidemia and increased hepatic lipid. Lifestyle measures (weight-bearing exercise, calcium and vitamin D supplementation) may also be advised in patients with reduced bone mineral density; whether bisphosphonate therapy is beneficial in RTHβ is unknown.

On the basis that maternal hyperthyroxinaemia may increase loss of wild-type fetuses,[161] in women with RTHβ and a history of recurrent miscarriage, antithyroid drug treatment from early pregnancy could be considered.[162] During pregnancy, if maternal FT4 does not exceed 50% above the upper limit of normal for gestational age, and fetal growth and heart rate remain normal, this may provide reassurance that significant fetal or neonatal hyperthyroidism is unlikely.[163]

KEY POINTS

- In asymptomatic resistance to thyroid hormone β patients, surveillance for dyslipidemia, metabolic syndrome, and low bone mineral density is recommended, as well as considering lipid-lowering therapy and lifestyle measures (e.g., weight loss, weight-bearing exercise, calcium and vitamin D supplementation) to prevent adverse metabolic and skeletal sequelae.
- β-blockade can ameliorate sympathetic and cardiac hyperthyroid symptoms in childhood and adults. Treatment with 3,5,3'-triiodothyroacetic acid, a centrally acting thyromimetic that lowers circulating thyroid hormone levels, is beneficial in patients with generalized hyperthyroid symptoms.
- Thyroid ablation, followed by subphysiological thyroxine replacement, may be warranted, but only in rare cases with life-threatening, thyrotoxic cardiac failure.

RESISTANCE TO THYROID HORMONE ALPHA

Background

Human TRβ and TRα exhibit marked amino acid sequence similarity, including in their hormone binding domains (80%); accordingly, with approximately 218 different receptor mutations known to be associated with RTHβ, the identification of homologous human TRα defects had been anticipated. Supporting this notion, murine transgenic models harboring different heterozygous TRα mutations are viable and exhibit recognizable abnormalities, but with minimal perturbation of thyroid function.[164,165] Such absence of an overt thyroid biochemical phenotype likely explains why the human disorder (RTHα) eluded discovery for a decade.[166,167]

Clinical Features

At birth, some features (e.g., macroglossia, poor feeding, hoarse cry, umbilical hernia) recognized in hypothyroidism have been noted.[168,169] Two patients were investigated in infancy for growth retardation that predominantly affected the lower segment.[166,167] Abnormal physical characteristics in the majority of cases include macrocephaly, broad facies, a flattened nose, prominent tongue, and thick lips.[166-170] Older children and adults have an excessive number of skin tags and melanocytic naevi in the head and neck area, possibly due to the hyperproliferative state of their normal cutaneous cells.[171]

Biochemical. The most consistent pattern of thyroid function tests comprises low or low-normal FT4 and high or high-normal FT3, resulting in an abnormally low T4/T3 ratio; in addition, reverse T3 levels can be subnormal. In a minority of patients, thyroid function tests (TSH, FT4, FT3) can be completely normal. A mild normocytic anemia, with normal hematinics and hemolytic indices, and raised muscle creatine kinase levels are a consistent abnormality.[166,168,169,172]

Skeletal. Radiographic abnormalities in childhood include delayed fontanelle fusion and excessively serpiginous cranial sutures ("wormian bone" appearance), together with delayed dentition.[166,167] Femoral epiphyseal dysgenesis was present in childhood[166] but not in adult life[168]; bone age can be delayed.[166,167] Cranial and cortical hyperostosis in long bones, together with increased bone mineral density, is present in most cases, especially in adults.

Neurocognitive. In childhood, patients showed delayed milestones (motor, speech). Slow initiation of motor movement, together with fine and gross motor incoordination, manifesting as dyspraxia or a broad-based, ataxic gait and slow, dysarthric speech are a consistent feature. IQ is variably reduced, being markedly subnormal in some cases but with other patients attaining educational qualifications.[168] In severe cases magnetic resonance imaging has documented cortical microencephaly, reduced cerebellar volume, and white matter tract

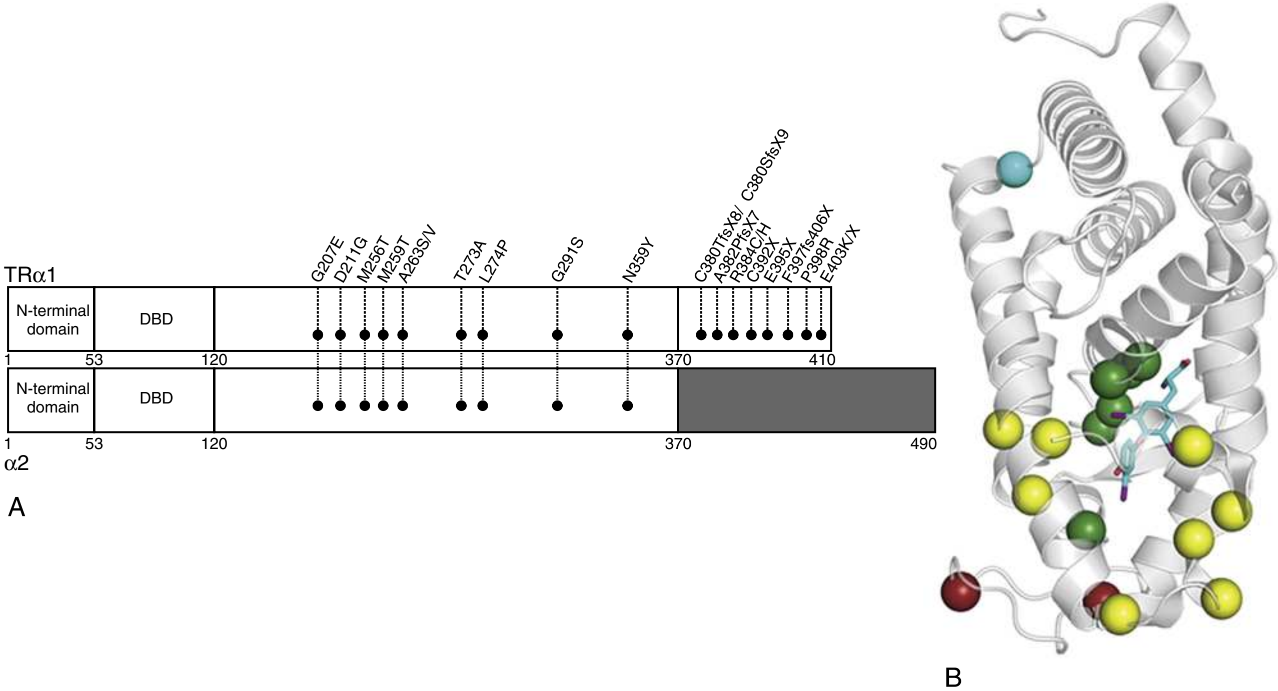

Fig. 81.5 **A,** A schematic representation of the domains of thyroid hormone receptor (TR) α1 and non-hormone-binding α2 proteins. Missense, frameshift, and premature stop mutations that only involve TRα1 or missense mutations that are common to both TRα1 and variant α2 proteins are shown. **B,** The crystal structure of the ligand-binding domain of TRα1 (Protein Data Bank Accession no. 2H77), showing the position of missense, frameshift, and premature stop mutations, color-coded according to the resistance to thyroid hormone b mutation clusters (Fig. 81.3) within which equivalent amino acids in TRβ reside.

density.[173] Genetic studies of a large autism cohort identified a pathogenic *THRA* mutation in one case,[174] and several *THRA* variants whose functional significance is not known have been found in a smaller cohort.[175]

Gastrointestinal. Reduced frequency of bowel movements is a common finding, with severe constipation being a significant problem in two cases.[166,168]

Cardiovascular. Bradycardia[166,168,169] is typical, with abnormal sympathovagal balance and indices of cardiac contractility in the hypothyroid range.[168]

Metabolic and endocrine. REE (metabolic rate) was low in most pati ents.[166,168,169] Both male- and female-to-offspring transmission of TRα defects has been recorded,[167,169] suggesting that fertility is not severely compromised.

KEY POINTS

- Resistance to thyroid hormone α, a disorder characterized by many features of hypothyroidism, including childhood neurodevelopmental delay, growth retardation, and skeletal dysplasia together with constipation and low metabolic rate, is likely to be underdiagnosed because it is associated with near-normal thyroid function tests.

Molecular Genetics

Twenty-one different heterozygous *THRA* mutations (frameshift/premature stop, missense), inherited from either parent or occurring *de novo*, have been documented in 36 cases (Fig. 81.4). Frameshift/premature stop TRa1 mutants fail to bind ligand, are devoid of transcriptional activity, and are associated with a severe clinical phenotype.[166-168] Similar to TRβ mutations in RTHβ, TRα1 mutants inhibit the function of their wild-type receptor counterparts in a dominant-negative manner when they are coexpressed; as has been delineated in RTHβ, constitutive binding of mutant TR to corepressors, with failure of corepressor dissociation and coactivator recruitment following T3 occupancy, likely mediates such dominant-negative inhibition (Fig. 81.3). Expression of TH-responsive target genes in mutation-containing patient peripheral blood mononuclear cells is blunted, suggesting that such dominant-negative inhibition occurs *in vivo.*[166,168]

Many RTHα cases involve *THRA* mutations that affect both TRa1 and TRa2 isoforms.[169,176-178] When studied in the TRα2 protein background, these mutations exhibit no added gain or loss of function, which correlates with absence of any discernible additional clinical phenotype attributable to mutant TRa2, in these patients.[169,176-178] In a single case,[179] highly unusual clinical features (micrognathia, clavicular agenesis, syndactyly) were not seen in a transgenic mouse model[180] and may be unrelated to the *THRA* defect.

Due to the absence of a pathognomonic diagnostic phenotype, highly deleterious receptor defects are likely overrepresented amongst current, disease-associated *THRA* mutations. Consonant with their known homology of TRα and TRβ proteins, most *THRA* mutations that cause RTHα are homologous to known mutations of the equivalent amino acid in *THRB*, causing RTHβ.[181]

Pathogenesis. Many clinical features (e.g., skeletal dysplasia, reduced intestinal motility, bradycardia) in RTHα patients are typical of untreated congenital or adult hypothyroidism. Skeletal abnormalities (growth retardation, delayed tooth eruption, patent cranial sutures, epiphyseal dysgenesis) and intestinal dysmotility in human RTHα are recapitulated in TRα1 mutant mouse models.[164,165] Abnormal thyroid function (low T4/T3 ratio, reduced reverse T3) in RTHα may reflect altered TH metabolism: higher hepatic DIO1 expression in

TRα1 mutant mice[165] may mediate increased T4 to T3 conversion and reverse T3 clearance; alternatively, decreased levels of DIO3 (which is known to be TRα1-regulated) could mediate altered TH metabolism. Differentiation of erythroid progenitors from RTHα patients or transgenic mice is impaired, with dysregulation of Gata-1 being implicated in the animal model.[182,183] Cortical microencephaly seen in adults with severe RTHα correlates with altered proliferation of cortical neural progenitors derived from patient's stem cells.[173] Idiopathic epilepsy seen in human cases[168,169] could be linked to aberrant development of GABAergic inhibitory interneurons in a murine model.[184]

KEY POINTS

- The disorder is mediated by heterozygous, dominant-negative thyroid hormone receptor (TR) α mutants, often homologous to known THRB mutations causing resistance to thyroid hormone β. Mutations involving both TRα1 and TRα2 proteins are not associated with any discernible added phenotype in patients.

Management

T4 treatment in RTHα is beneficial, improving growth (total height and subischial leg length), increasing basal metabolic rate (and thereby limiting weight gain), lowering elevated creatine kinase levels, and enhancing well-being.[168,169,172,178,181] Addition of growth hormone to T4 therapy in childhood does not result in further improvement in growth.[172] In cases harboring mutant TRα1 whose dysfunction is reversible at higher TH levels, treatment from early childhood may have ameliorated their phenotype; in adult life these individuals report improved dyspraxia, constipation, and self-confidence.[169] In virtually all cases, T4 treatment does not improve anemia.

Following T4 treatment in physiological dosage, TSH levels suppress readily, with elevation of FT3 to supraphysiological levels, consonant with preserved TH sensitivity within the hypothalamic-pituitary-thyroid axis; serum sex hormone-binding globulin rises slightly from high-normal baseline levels[168]; conversely, cardiac parameters, REE, and muscle creatine kinase levels are less responsive.[168,169] Overall, these observations are consonant with hormone resistance in organs (e.g., myocardium, skeletal muscle, gastrointestinal tract) expressing predominantly TRα1, with preservation of TH sensitivity in TRβ-expressing tissues (hypothalamus, pituitary, liver).

Increasing use of NGS to identify a genetic basis for phenotypes that are known to be RTHα-associated will likely increase ascertainment of the disorder, as well as identify new clinical manifestations associated with receptor defects. Future identification of specific biomarkers in RTHα have the potential to improve its diagnosis, enabling earlier commencement of T4 therapy to improve outcome.

KEY POINTS

- Thyroxine therapy is beneficial, improving linear growth and limiting excess weight gain in childhood, alleviating constipation and improving well-being.

Surgical Management of Thyroid Disease

Pia Pace-Asciak, Jonathan O. Russell, Christopher R. Razavi, Vaninder K. Dhillon, Ved Tanavde, Mohammad Shaear, and Ralph P. Tufano

OUTLINE

History of Thyroid Surgery, 1359
Relevant Surgical Anatomy, 1360
- The Recurrent Laryngeal Nerve, 1360
- The External Branch of the Superior Laryngeal Nerve, 1360
- Parathyroid Glands, 1361
- Lymphatics, 1361

Imaging For Surgical Planning, 1361
- Ultrasound, 1361
- Axial Imaging, 1361

Molecular Testing and Its Use For Surgical Planning, 1362
- Indeterminate Nodules, 1362
- Planning the Extent of Surgery, 1363

Diseases Of The Thyroid and Surgical Procedures To Consider, 1363
- Graves Disease, 1363
- Hashimoto Thyroiditis, 1363

Developmental Abnormalities of the Thyroid Gland And Their Surgical Management, 1363
- Thyroglossal Duct Cyst and Surgical Excision, 1363
- Thyroid Hemiagenesis and Agenesis, 1363
- Ectopic Thyroid and Surgical Excision, 1364
- Lingual Thyroid, 1364
- Suprahyoid and Infrahyoid Thyroid, 1364
- Substernal Goiter, 1364

Thyroid Cancer And The Surgical Management, 1365
- Papillary Thyroid Cancer, 1365
- Follicular Thyroid Cancer, 1365
- Noninvasive Follicular Thyroid Neoplasm with Papillary-Like Nuclear Features, 1365
- Hurthle Cell Thyroid Cancer, 1365
- Medullary Thyroid Cancer, 1366
- Anaplastic Thyroid Cancer, 1366
- Radioactive Iodine Therapy, 1367

Indications For Surgery of the Thyroid Gland, 1367
- Indications for Lobectomy versus Total Thyroidectomy, 1367
- Indications for Active Surveillance, 1367
- Indications for Remote Access Surgery, 1367
- Indications for Prophylactic Central Neck Dissection, 1367
- Indications for Therapeutic Central Neck Dissection, 1367
- Indications for Lateral Neck Dissection, 1367

Transoral Approach To Thyroidectomy, 1368
Open Surgical Techniques, 1368
- Lobectomy and Total Thyroidectomy, 1368
- Retrograde Medial Approach to the Thyroid Dissection, 1369
- Central Neck Dissection, 1369
- Lateral Neck Dissection, 1370

Minimally Invasive Techniques, 1370
- Radiofrequency Ablation Technique, 1370

Surgical Complications, 1370
- Recurrent Laryngeal Nerve Injury, 1370
- Hypoparathyroidism, 1371
- Spinal Accessory Nerve Injury, 1371
- Greater Auricular Nerve Injury and Sensory Cervical Rootlets, 1371
- Other Cranial Neuropathies, 1371
- Chyle Leak, 1371
- Cosmesis, 1371
- Complications Associated with Transoral Surgery, 1371
- Complications Associated with Radiofrequency Ablation, 1372

HISTORY OF THYROID SURGERY

The history of thyroid surgery dates back thousands of years, to as early as 952 AD, when al-Zahrawi (Albucasis) described the first thyroidectomy for resection of a large goiter.[1] Even though surgical treatment of a goiter was recognized, the developments that led to the contemporary era of thyroid surgery only began a century ago. Initially, thyroid surgery was fraught with complications, including hemorrhage, infection, and injury to the surrounding structures. With a mortality rate of over 40%, the French Academy of Medicine banned thyroid operations in 1850.[1] A turning point was reached at the end of the nineteenth century when Swiss surgeon Theodor Kocher focused on ligation for hemostasis, knowledge of the surrounding anatomy, and antisepsis.

Thyroid surgery was performed well before the physiology of the thyroid and parathyroid glands were understood. Kocher, a pupil of Theodor Billroth, was instrumental in bridging the physiological importance of the thyroid with surgical technique. He recognized that patients developed "cachexia strumipriva," also known as hypothyroidism, after total thyroidectomy, which led Kocher to perform mostly thyroid lobectomies to avoid patients developing this condition and "sending patients with a goiter into a vegetative existence."[1]

For his contributions to the field of thyroid surgery, Kocher was awarded the Nobel Prize in 1909, with morbidity dropping to less than 1% during his career.[1] Although thyroid surgery has undergone minor modifications, modern thyroid surgery has used much the same approach and technique since the late nineteenth century. Today, conventional transcervical thyroidectomy, when completed by an experienced, high-volume thyroid surgeon, has an exceedingly low mortality rate, with relatively little morbidity.[2]

As the rate of thyroid cancer continues to grow worldwide, clinicians forge ahead to find innovative ways to treat thyroid disease in a minimally invasive and personalized way. Understanding the way in which thyroid disease behaves at a molecular level can help clinicians to effectively target the disease, more or less aggressively, depending on the patient's risk of recurrence. In an era of "personalized medicine," patient care is tailored to meet the needs of the individual patient, rather than the "one size fits all" traditional approach. Options may include surveillance, the traditional midline incision approach that Kocher fathered, or no cutaneous incision at all through remote access surgery using an endoscope or by radiofrequency ablation (RFA) without removing the thyroid gland at all. With improved imaging, biochemical testing, and molecular testing, as well as surgical instrumentation, the pendulum has swung from treating all thyroid disease with one type of surgical approach to a more selective approach that risk-stratifies the disease, as well as the patient's needs.

RELEVANT SURGICAL ANATOMY

The Recurrent Laryngeal Nerve

Surgical Landmarks. Various challenges can be encountered intraoperatively, such as a bulky goiter with multiple nodules, a recurrent laryngeal nerve (RLN) that is encased by tumor, bleeding, or a congenital variation such as a nonrecurrent laryngeal nerve (NRLN). Stable landmarks can help guide the surgeon to avoid inadvertent injury to the RLN. Additionally, intraoperative nerve monitoring is a valuable adjunct for confirming the identification and function of the RLN in these situations, and is used by most high-volume thyroid surgeons in the Western world.[3]

Berry's Ligament. Berry's ligament (BL) and the tracheoesophageal groove (TEG) can help with identification of the RLN during surgery.[4] Up to 80% of the time, the RLN is located superficial to BL, and much less commonly it is found deep to BL (15%).[5] This relationship between BL and the RLN tends to be a symmetrical on either thyroid lobe. Care should be taken when dissecting BL before identification of the RLN, for less common instances when the RLN pierces BL.[6] It is common for anterior and posterior branches of the nerve to bifurcate within BL. In such cases, the anterior or medial branch is most likely to be the motor branch of the nerve, while the posterior branch is sensory.

Tubercle of Zuckerkandl. The tubercle of Zuckerkandl is a pyramidal extension of the thyroid lobe that is located more laterally and posterior on the thyroid.[7] It is a thickening of the lateral aspect of the thyroid gland and is closely connected to the superior parathyroid gland. Surgically, the tubercle of Zuckerkandl is significant, as it may represent a landmark for identifying the RLN, which runs beneath the projection as it enters the cricothyroid joint.[7]

Cricothyroid Joint. The cricothyroid joint is one of the most consistent and fixed landmarks for identification of the RLN entry into the larynx. Palpation of the inferior horn of the thyroid cartilage indicates the depth of the RLN, which is reliable regardless of thyroid pathology or the presence of congenital variations.[8] Variability in the angle of the RLN can be found as it courses toward the cricothyroid junction; however, identification of BL and the cricothyroid joint will yield the RLN just posterior to these structures.[8,9]

Inferior Thyroid Artery. Commonly, the posterior division of the inferior thyroid artery (ITA) has been found to accompany the RLN.[10] The relationship of the ITA to the RLN tends to be variable and asymmetric when the right and left sides are compared. The most common presentation on the left side is for the RLN to be posterior to the ITA, and on the right side, the RLN is anterior to the ITA.[11]

Factors that Make the Recurrent Laryngeal Nerve Vulnerable to Injury

Nonrecurrent Laryngeal Nerve. A NRLN is a rare finding with an incidence of 0.3% to 0.8% on the right and 0.004% on the left side.[12] An NRLN on the right side is almost always associated with a vascular anomaly. The presence of an aberrant right subclavian artery (arteria lusoria) from the descending aorta is associated with the presence of a right NRLN. A left NRLN is extremely rare, and when present, it associated with *situs inversus* or a right-sided aortic arch.[12]

The Proximity of the Recurrent Laryngeal Nerve to the Thyroid Gland. The RLN can be found in the TEG approximately 65% of the time. Less commonly, it may be lateral or anterior to the TEG when large nodules or substernal goiters are present.[5] Sometimes the thyroid parenchyma may envelope the RLN. Again, nerve identification is considered necessary by most high-volume surgeons. In a landmark paper, Lahey reported a significantly lower incidence of RLN injury following thyroidectomy with clear visualization of the RLN than after operation without nerve identification.[13]

Deformities from Large Thyroid Nodules. In the presence of large nodules and substernal goiters, the laryngeal nerves may be pushed more anteriorly than expected or stretched from compression of a large goiter. Careful blunt dissection is recommended for a safe approach until the nerve is identified.

Extralaryngeal Nerve Branching of the Recurrent Laryngeal Nerve. Variations in the branching of the RLN are common and can increase the risk of transient injury 2-fold to 15.8% compared with a nonbranched RLN (8%).[14] The RLN may branch before the nerve enters into the larynx, near BL in approximately 30% to 78% of cases.[15] The branching may differ from side to side, but most often the motor innervation comes from the anterior branch, and the sensory innervation is posteriorly.[15] If the sensory division is ligated, the patient may experience postoperative dysphagia; however, if the anterior branch is ligated, the patient is likely to experience vocal fold paralysis.

Inferior Thyroid Artery. Given the variable location of the ITA in relation to the RLN, it is recommended that the nerve is identified first prior to ligating its branches.

The External Branch of the Superior Laryngeal Nerve

The right and left superior laryngeal nerve (SLN) exit from the vagus and course with the superior thyroid artery until approximately 1 cm before the superior pole, where they enter the capsule of the superior pole of the thyroid.[16,17] The SLN gives off two branches. The first is the external branch, which is primarily motor in function and innervates the cricothyroid muscles.[16,17] The cricothyroid muscle causes the thyroid cartilage to tilt, which tenses the vocal cord and raises the pitch or projection of the voice. The second is the internal branch, which is sensory to the larynx (subglottis) and enters the thyrohyoid membrane, which can result in dysphagia if the sensory branch is injured.[16]

Factors that Make the External Branch of the Superior Laryngeal Nerve Vulnerable to Injury. In most cases, the external branch of the SLN (EBSLN) lies close to the vascular pedicle of the superior thyroid vessels. In some patients, the EBSLN lies on the anterior surface of the thyroid lobe, making the possibility of damage during thyroidectomy even greater.[17] Cernea et al. proposed a classification system for describing the proximity of the EBSLN with the superior thyroid vessels.[18] In the type 1 configuration, the EBSLN crosses the superior thyroid vessels 1 cm or more above the horizontal plan, passing the upper border of the superior thyroid pole. In type 2a, the EBSLN crosses the superior thyroid vessels less than 1 cm above the plane, and in type 2b, the EBSLN crosses the superior thyroid vessels below the plane. The highest-risk configuration is the type 2b nerve, making the nerve vulnerable to iatrogenic injury, particularly for enlarged goiters, because it travels close to the thyroid gland. Even placement of a tie close to the thyroid pole could put the nerve in jeopardy.[18] Thus, care should be taken when ligating the superior vascular pedicle of the thyroid by aiming to dissect close to the thyroid capsule after the EBSLN has been identified, as injury can occur in up to 30% of cases.[16,17] Another way to minimize injury is to visualize the cricothyroid muscle so identification and protection of the EBSLN is possible.

Parathyroid Glands

Even though normal parathyroid glands are typically the size of a grain of rice, they hold the utmost physiological importance in their regulation of calcium hemostasis through the secretion of parathyroid hormone (PTH). There are typically four glands present, two on each side. Rarely, supernumerary glands have been described.[19] Each gland normally weighs 30 to 40 mg. The delicate blood supply of these glands and their small size makes them vulnerable to accidental removal or devascularization during thyroidectomy.[19]

Typically, the inferior parathyroid glands are located below the ITA and anterior to the RLN along the posterior side of the thyroid lobe,[20] whereas the upper parathyroid glands are found above the ITA and usually adjacent to the posterior surface of the middle part of the thyroid lobe, near the RLN as it enters toward the cricothyroid joint within 1 cm of the RLN insertion.[20] The lower parathyroid glands embryologically arise from the third pharyngeal pouch, and their distribution in the neck may be variable, whereas the upper parathyroid glands are derived from the fourth pharyngeal pouch.

Parathyroid glands have a tan or salmon color. With surgical experience, these glands become easier to differentiate from lymph nodes, fat, or thyroid nodules. Frozen section examination during surgery can be helpful in their identification. Additionally, novel instruments that rely on the inherent autofluorescent properties of parathyroid tissue are becoming more commonplace in thyroid surgery.[21]

Lymphatics

The central neck (levels VI and VII) is the primary drainage site for metastatic spread of thyroid carcinoma. Approximately 35% of patients presenting with PTC have cN1 disease.[15] However, up to 80% of patients presenting with cN0 disease may harbor microscopically positive lymph nodes.[15] The lateral neck compartments (levels I–V) can be involved, but less frequently than the central neck. Generally, thyroid cancer spreads sequentially from the central neck to the lymph nodes of the lateral neck. Less commonly, metastasis is found in the retropharyngeal or retroesophageal nodes. Rarely, involvement is seen in the mediastinal lymph nodes.[15] Of note, up to 18% of patients can have skip metastasis to levels II and III of the lateral neck without central neck metastasis, arising from a superior pole cancer.[22] Only clinically detectable lateral nodal metastasis are significant.

Central Neck. The central compartment (level VI) is bounded superiorly by the hyoid bone, laterally by the carotid arteries, inferiorly by the sternal notch and innominate artery, anteriorly by the superficial layer of the deep cervical fascia, and posteriorly by the deep layer of the deep cervical fascia or prevertebral fascia. The central neck is divided further into subcompartments, which can be independently dissected during central neck dissection (CND) for PTC and is based on anatomical location. These subcompartments include: (1) the prelaryngeal (Delphian) lymph nodes, (2) the pretracheal lymph nodes, (3) the right paratracheal lymph nodes, and (4) the left paratracheal lymph nodes.[15,23] Level VII lymph nodes are associated with the brachiocephalic vein and innominate artery.[15] The lowest point in the CND is defined by the innominate artery on the right (at its point of tracheal crossing) and the corresponding axial plane on the left.

The right and left paratracheal regions differ anatomically and in terms of the lymph node distribution around the RLN. The lymphatic tissue in the right paratracheal region is more anterior and posterior to the right RLN due to the presence of the innominate artery, which crosses anterior to the trachea.[15,24] Thus, to completely remove the lymphatic tissue in the right paratracheal compartment, the surgeon needs to transpose the RLN in order to dissect both anterior and deep to the nerve to avoid disease recurrence in this unfavorable location.[24,25] On the other hand, the left RLN runs in a more cranial to caudal direction in the TEG versus a more oblique orientation found on the right. As a result, the lymphatic tissue in the left paratracheal region is located anterior to the RLN and the esophagus but medial to the carotid artery.[15]

Lateral Neck. A constant group of lymph nodes (the lateral neck compartment) lies along the internal jugular vein (IJV) on each side of the neck, and may be divided into levels I to V, corresponding with the submandibular and submental nodes (level I); upper, middle, and lower jugular nodes (levels II, III, and IV); and posterior triangle nodes (level V).[23] The boundaries of the level I compartment are defined by the mandible superiorly, the stylohyoid muscle posteriorly, and the anterior belly of the digastric muscle anteriorly. This level is further subdivided into level Ia, the submental triangle (bounded by the anterior bellies of the digastric muscle and the hyoid bone) and level Ib, containing the submandibular gland and its nodes.[23] Level II, which contains the jugulodigastric lymph nodes, is located in the upper third of the jugular vein, with the stylohyoid muscle as the anterior border and the sternocleidomastoid muscle (SCM) as the posterior border. The spinal accessory nerve runs obliquely and subdivides level IIa, which is anterior to the nerve, from level IIb, which is posterior to the nerve. Level III contains the midjugular nodes, with the hyoid defining the superior border and the cricoid cartilage as the inferior boundary. The anterior limit is the sternohyoid muscle, and the posterior boundary is the SCM. Level VI, the lower jugular nodes, are bounded by the inferior aspect of the cricoid cartilage superiorly and the clavicle inferiorly. The anterior limit is the sternohyoid muscle, and the posterior limit is the SCM. Level V, the posterior compartment, is bounded anteriorly by the SCM and posteriorly by the trapezius muscle. The plane that divides the two compartments is the inferior border of the cricoid cartilage, which subdivides it into level Va, containing the nodes from the spinal accessory nerve and located superiorly; whereas level Vb, located inferiorly, contains the transverse cervical and supraclavicular nodes.[23]

KEY POINTS

- Various surgical landmarks (Berry's ligament, Tubercle of Zuckerhandl, Cricothyroid joint, and the Inferior Thyroid artery) can help surgeons identify the RLN or the EBSLN (Cricothyroid muscle and Superior Thyroid artery).

IMAGING FOR SURGICAL PLANNING

Ultrasound

Ultrasound is the first-line imaging modality for evaluating known or suspected thyroid cancer, as well as overall evaluation of the thyroid gland.[26] Knowing the sonographic pattern of the nodule is key in establishing whether to investigate further (Table 82.1).

Axial Imaging

Cross-sectional imaging such as computed tomography (CT) scan or magnetic resonance imaging (MRI) may have a supplemental role in preoperative imaging for thyroid cancer in the minority of cases and has its advantages over thyroid ultrasonography.

TABLE 82.1 Comparison of ATA with ACR-TIRADS Classification

2015 ATA Classification	2017 ACR TI-RADS Classification
High suspicion	**TR5 (high suspicion)**
70%–90% risk of malignancy	
Solid hypoechoic thyroid nodules with one or more of following:	
Irregular margin	
Microcalcification	
Taller than wide	
Rim calcification with small, extrusive soft-tissue component	>20% risk of malignancy
Extrathyroidal extension	TI-RADS score of 7 points or more
Intermediate suspicion	**TR4 (moderate suspicion)**
10%–20% risk of malignancy	5%–20% risk of malignancy
Hypoechoic nodule with smooth margin	TI-RADS score of 4–6
Low suspicion	**TR3 (mild suspicion)**
5%–10% risk of malignancy	5% risk of malignancy
Isoechoic or hyperechoic solid nodule or partially cystic nodule with eccentric solid areas	TI-RADS score of 3
Very low suspicion	**TR2 (not suspicious)**
<3% risk of malignancy	≤2% risk of malignancy
Spongiform or partially cystic nodules	TI-RADS score of 2
Benign	**TR1 (benign)**
Benign: pure cyst	≤2% risk of malignancy
	TI-RADS score of 0

Computed Tomography Scan. CT with intravenous contrast is the most widely accepted form of axial imaging. Of note, the intravenous contrast used for CT scan contains a large load of iodine, which may interfere with radioiodine (RAI) scanning and therapy for 6 to 8 weeks. The use of iodinated contrast may delay postoperative treatment with RAI, but the usefulness in preoperative planning justifies a delay when indicated.[31]

The circumstances where axial imaging is indicated include: (a) clinical or sonographic evidence of an invasive primary tumor, (b) presence of a large primary tumor or bulky nodal disease incompletely imaged with ultrasound, (c) presence or extension of nodal disease outside of the central neck, and (d) absence of sonographic expertise in evaluation of cervical lymph nodes.[32] Cross-sectional imaging also has a role in identification of the substernal or suprasternal extent of benign thyroid disease.

Magnetic Resonance Imaging. MRI has specific applications for staging and surveillance, as well as localization of metastatic disease for thyroid cancer, but tends not to be used for benign disease.[31] Given that CT scan is more sensitive for detecting small metastases to lymph nodes and the lungs, generally, MRI does not play a large role in the initial work-up of thyroid disease and is reserved for more complicated cases. MRI imaging of the neck may be considered in thyroidectomy patients with rising serum thyroglobulin (Tg) levels and a history of RAI therapy and neck dissection.[33]

Positron Emission Tomography Scan. Functional imaging known as (^{18}F)-fluorodeoxyglucose–positron emission tomography (FDG-PET) scan is a nuclear medicine test that detects malignancies based on glucose hypermetabolism. Routine preoperative FDG-PET scanning is not recommended for indeterminate nodules or locoregional thyroid carcinoma, as glucose uptake can be nonspecific when inflammation is present, such as in Hashimoto thyroiditis.[26] Generally, PET scan is best used in more advanced disease if distant metastases are suspected and to help stage a patient before further treatment.[32]

Thyroid incidentalomas detected by FDG-PET scan are infrequent but can be picked up on imaging during work-up for an unrelated problem. The literature reports a detection rate of 0.1% to 4.3% for incidental findings of thyroid focal uptake identified by FDG-PET/CT, with a risk of malignancy of between 10.3% and 80%.[34] Given the wide range for potential malignancy, it is prudent to follow up a positive PET scan with a dedicated thyroid ultrasound to further delineate "incidentalomas."

Thyroid Scintigraphy. When the thyroid-stimulating hormone (TSH) is low (patient is hyperthyroid), thyroid scintigraphy (^{123}I or technetium-99m pertechnetate) or RAI scanning is the appropriate imaging modality to determine if a toxic nodule(s) is present.[35] Scintigraphy provides added information on the functional status of the thyroid gland or nodule, a feature that cross-sectional imaging lacks. Other indications for scintigraphy are for evaluation of a patient suspected of having an ectopic thyroid gland and to determine whether the lingual or substernal tissue is functional.[36] Further, patients who have had thyroid surgery for cancer will have whole-body scintigraphy to define the amount of thyroid remnant, which allows for Tg monitoring for recurrence postoperatively.

KEY POINTS

- Ultrasound is the imaging modality of choice for evaluating thyroid nodules. Axial Imaging (CT scan of MRI) is reserved for primary or recurrent invasive thyroid cancer, lateral neck disease or retrosternal extension.

MOLECULAR TESTING AND ITS USE FOR SURGICAL PLANNING

Indeterminate Nodules

Molecular testing is a topic of debate, as the current paradigm suggests that, among multiple molecular tests, there is no one test that can guarantee carcinoma from a histologically indeterminate nodule. Molecular testing should only be used if it is going to add to the surgical decision-making process for indeterminate Bethesda cytology results. The following scenarios are examples where molecular testing is unlikely to rule out malignancy: a) nodules that yield insufficient material for diagnosis, benign nodules, suspicious for malignancy, or malignant nodules on cytological evaluation; b) nodules with strong clinical or radiological findings suggestive of a thyroid malignancy; c) indeterminate nodules greater than 4 cm, a size at which nodules may harbor an occult thyroid cancer owing to fine-needle aspiration (FNA) sampling error; d) nodules causing compressive symptoms for which surgery would be recommended regardless; and e) patients who defer surgery (i.e., uncomfortable with conservative management of a nodule regardless of the test result.[29] Molecular testing is best suited to patients with indeterminate Bethesda cytology and minimal clinical suspicion for malignancy and if the result would alter decision-making.

Planning the Extent of Surgery

Some centers use molecular testing to anticipate aggressive tumor types, which can in turn be helpful for planning the extent and timing of surgery. The presence of *BRAF* V600E, *RET/PTC1* rearrangement, or *TERT* mutation may make the discussion of surgery easier with a patient who has an indeterminate Bethesda score, knowing that these molecular markers are associated with more aggressive cancers 65% of the time.[43]

KEY POINTS

- Molecular testing should only be used if it is going to add to the surgical decision-making process for indeterminate Bethesda cytology results.

DISEASES OF THE THYROID AND SURGICAL PROCEDURES TO CONSIDER

Graves Disease

In the United States, the prevalence of hyperthyroidism is 1.2%.[35] The most common causes of hyperthyroidism are Graves disease, toxic multinodular goiter (TMNG), and toxic adenoma (TA).[35]

Management of thyrotoxicosis includes beta blocker therapy, whereas Graves disease, TMNG, and TA can be managed with RAI, antithyroid drugs (ATDs), or surgery.[35] Surgery tends to be reserved for patients with a large goiter causing compressive type symptoms or for those who have severe hyperthyroidism that is difficult to control with ATDs or RAI.[44] Patients with an allergy to ATDs, who are of reproductive age and do not wish to pursue RAI, or who have a thyroid nodule that is suspicious for malignancy can also be considered for total thyroidectomy or near-total thyroidectomy.

Malignancy is less likely to occur in hyperfunctioning thyroid nodules. However, an updated systematic review demonstrates that the overall rate of thyroid malignancy in patients with hyperthyroidism (Graves disease, TMNG, or single toxic nodules) is 8.5% (range 0.8%–32.4%).[45] Patients with Graves disease and coexisting thyroid nodules are five times more likely to be diagnosed with thyroid carcinoma than those patients with Graves disease without nodules.[46] Thus, during the work-up for hyperthyroidism, nodules should be evaluated for concurrent thyroid malignancy with FNA biopsy.[46]

Surgical resection involves subtotal thyroidectomy, near-total thyroidectomy, or lobectomy with contralateral subtotal or near-total lobectomy (Dunhill procedure).[36] Evidence shows that, if a remnant of 2 to 2.5 g or more of thyroid tissue is left behind, a recurrence rate of approximately 12% at 10-year follow-up exists.[47] Hence, leaving only a small amount of tissue behind, if at all, is recommended, along with postoperative thyroxine treatment, especially in young patients where the rate of recurrence of thyrotoxicosis tends to be higher. When operating on patients with Graves and severe ophthalmopathy, near-total or total thyroidectomy is the treatment of choice for improvement in eye symptoms.

Hashimoto Thyroiditis

Hypothyroidism is found in 4.6% of the US population (0.3% clinical and 4.3% subclinical).[48] Of the different causes of hypothyroidism, Hashimoto thyroiditis, also known as chronic autoimmune thyroiditis, is one of the most common in iodine-sufficient areas of the world, characterized by antibodies to thyroid peroxidase and Tg.[48]

Hashimoto's itself or hypothyroidism is not an indication for surgery, unless there are suspicious nodules present on ultrasound, pressure symptoms, or concerns of cosmesis. However, Heggie et al. found that patients with Hashimoto's were more likely to have pressure symptoms, even though their glands were significantly lighter compared with those in the larger nonthyroiditis cohort.[49] In their retrospective series, 90% of patients with Hashimoto's had significant improvement in their pressure symptoms postthyroidectomy. Thus, surgery may be considered in patients with significant pressure symptoms with a diagnosis of Hashimoto's, regardless of the size of the goiter.[49]

KEY POINTS

- For symptomatic Graves' disease, surgical resection can involve a subtotal thyroidectomy or near-total thyroidectomy. Although Hashimoto's disease itself is not an indication for surgery, patients with pressure symptoms or suspicious nodules may be considered for surgical resection.

DEVELOPMENTAL ABNORMALITIES OF THE THYROID GLAND AND THEIR SURGICAL MANAGEMENT

Thyroglossal Duct Cyst and Surgical Excision

A thyroglossal duct cyst (TGDC) is a congenital anomaly formed during the embryological development of the thyroid gland. As the thyroid descends, its pathway of descent forms the thyroglossal duct tract, which disappears by the tenth week of gestation. If the tract persists and fails to obliterate anywhere along the pathway of descent, a midline cyst persists known as a TGDC.[50] If a distal remnant of the tract persists, then the pyramidal lobe is formed. TGDC can be seen at birth in about 25% of cases, with approximately one third becoming apparent after 30 years of age.[50] Patients present with a painless, midline cystic neck mass localized next to the hyoid bone (60%), between the hyoid bone and base of tongue (24%), between the hyoid and pyramidal lobe (13%), or intralingually (3%).[51,52] The cyst can become repeatedly infected and at times rupture, developing a persistent fistula or sinus tract to the outside skin or into the oral cavity. Physical exam is diagnostic, as the cyst moves cranially with swallowing or protrusion of the tongue.

In the wall of a TGDC is the second most common place for ectopic thyroid tissue.[53] If a solid component is found in the cyst, this may be the only functional thyroid tissue present, and follow-up TSH levels should be obtained pre- and postsurgery, as well as an ultrasound of the thyroid. The incidence of thyroid carcinoma in a TGDC is less than 1%, which may be less than expected, because excision is often done during childhood before a malignancy has had a chance to form.[53] In adults, there have been reported cases of incidental papillary thyroid carcinoma (PTC) found within the cysts, at a rate as high as 13% to 14%.[54] In a systematic review of the literature, the most common pathologic diagnosis was papillary cancer, at 92.1%, followed by squamous cell carcinoma, at 4.3%.[55] In such cases, there is an associated risk factor present, such as previous low-dose external beam irradiation of the head and neck in infancy or childhood as a trigger.

The treatment of choice for TGDC to avoid recurrence is the Sistrunk procedure. A Sistrunk procedure is the comprehensive excision of the cyst and its tract, which includes resection of the central portion of the hyoid bone as well as the tract up to the base of tongue. This procedure is necessary because the thyroglossal duct is intimately associated with the central part of the hyoid bone. An incision is made on the skin over the mass, and dissection is done bluntly to isolate the cyst and then the hyoid bone. Excision up to the base of tongue results in cure in most cases.[52] If a fistula tract connects to the skin, this should be excised as well to avoid recurrence.

Thyroid Hemiagenesis and Agenesis

Thyroid hemiagenesis (THA) is a rare congenital disorder that is characterized by the absence of one thyroid lobe. If the median thyroid anlage fails to develop, the result is athyreosis. Often THA is picked up incidentally on ultrasound, and less frequently on clinical exam, because most patients are euthyroid and asymptomatic. Left-sided isolated agenesis is the most common presentation (80%); however, combined THA of the right lobe with absence of the isthmus can occur, but less frequently.[56] When operating on a thyroid where hemiagenesis is noted, the parathyroid glands will remain intact, given their separate embryologic origin from the thyroid (third and fourth pharyngeal pouches).

Rarely, the thyroid gland fails to develop altogether, resulting in athyreosis. If left untreated in the newborn, this can lead to cretinism.

Ectopic Thyroid and Surgical Excision

Ectopic thyroid tissue is the most common cause of congenital hypothyroidism.[41] Failure of thyroid descent occurs in 1 out of 200,000 normal subjects and 1 out of 6000 patients with thyroid disease.[57] Ectopic thyroid is functioning thyroid tissue that can be found anywhere along the normal pathway of descent, from the foramen cecum down to the pretracheal region. Ectopic tissue can result in a lingual thyroid in a suprahyoid, infrahyoid, or intratracheal location. Less commonly, the entire thyroid gland can descend into the superior mediastinum behind the sternum, adjacent to the aortic arch or between the aorta and pulmonary trunk, within the upper portion of the pericardium, and even within the interventricular septum of the heart.[36] Care must be taken when surgically removing ectopic thyroid tissue, as it may be the only functioning thyroid tissue present. This is an important aspect to discuss with patients preoperatively, regarding the potential for a lifetime of thyroid hormone replacement therapy.

Lingual Thyroid

A lingual thyroid is a rare finding and is estimated to occur in 1 out of 3000 cases of thyroid disease.[58] However, it represents the most common site for functioning ectopic thyroid tissue. In 75% of patients with a lingual thyroid, it is their only functioning tissue due to the absence of normal cervical thyroid, or it functions poorly, resulting in hypothyroidism.[35] Malignant transformation of the lingual thyroid is rare (1 per 100); however, when it does occur, papillary or follicular carcinoma are the likely subtypes.[59]

The presence of hypothyroidism may cause the mass to enlarge, causing dysphagia, dysphonia, dyspnea, or a sensation of choking.[59] Rarely is a lingual thyroid associated with hyperthyroidism. Flexible nasopharyngoscopy shows the presence of a submucosal mass at the base of the tongue with prominent vascular markings akin to thyroid tissue. Radionuclide scanning can confirm the diagnosis. Up to 70% of patients require thyroid hormone replacement to treat their hypothyroidism, which can potentiate involution of the ectopic tissue and improve symptoms.[60] However, symptomatic patients who fail medical treatment may require surgical excision. Transoral surgical access to the tongue base is challenging to gain appropriate visualization in a narrow working space. Open approaches such as labiotomy, mandibulotomy, tongue-split, or cervical pharyngotomy provide exposure, but at the cost of being invasive.[37-40] Transoral robotic-assisted surgery (TORS) has emerged as a minimally invasive approach to the oropharynx and hypopharynx, with decreased morbidity that provides exceptional 3D visualization and instrument navigation.[40] Prisman et al. describe TORS-assisted excision of an ectopic lingual thyroid gland as safe and feasible.[61]

Suprahyoid and Infrahyoid Thyroid

Similar to a lingual thyroid gland, the descent of thyroid tissue can be arrested in the midline position above or below the hyoid bone. An enlarging mass commonly occurs during infancy or childhood, or later in life. Often, this mass is mistaken for a TGDC because it is in the same anatomic position. Prior to surgical removal, it is recommended that ultrasound of the neck is done to ensure the presence of a normal thyroid gland.

Substernal Goiter

Most substernal goiters originate in the neck and then “fall” or descend into the mediastinum due to gravity, rather than from aberrant thyroid tissue that was embryologically determined. Isolated intrathoracic thyroid masses are rare but occur in 5.8% of all mediastinal masses.[62] Up to 40% of substernal goiters are asymptomatic and found incidentally.[62] The most accepted definition of a retrosternal goiter is a thyroid gland that extends below the thoracic inlet.[62] A mediastinal mass can also be described by its association with the aortic arch or whether it reaches the level of T4 on a chest x-ray, or whether more than 50% of the gland extends below the thoracic inlet.[62]

Most substernal goiters are discovered incidentally on routine chest radiography in patients who are completely asymptomatic. If symptoms are present, the most common symptom when the thyroid extends below the thoracic inlet is dyspnea from tracheal displacement or compression that may or may not be positional.[62] The second most common symptom is dysphagia from esophageal compression, mostly to solids, and can be associated with laryngopharyngeal reflux.[62] Dysphonia is less common but can occur due to compression on the RLN, which can be assessed by flexible nasopharyngoscopy preoperatively. Even less frequently, a substernal goiter can cause superior vena cava syndrome, which often shows the presence of Pemberton sign.[62] A positive sign includes facial plethora, jugular vein distension, and symptoms of dyspnea when the patient lifts their arms above their head for a few minutes.[27]

When patients present in acute airway distress from tracheal compression due to their enlarged goiter, early surgical intervention is the preferred approach.[89] In a systematic review, preoperative positional dyspnea (defined as difficulty breathing at rest but improved by position change) was improved or resolved in 82.4% of cases overall post-thyroidectomy, in 65% of patients with cervical goiter, and in 88% of patients with substernal goiter.[94]

When faced with a large goiter causing tracheal compression and/or deviation, most patients can be easily intubated, because it is often the larynx that is misplaced. The equipment that should be available in the room to manage the difficult airway includes a rigid bronchoscope, fiberoptic intubation equipment, video laryngoscopes, and a laryngeal mask airway (through which a fiberoptic intubation can be performed).[89] The surgeon should be in the room on induction in the event that an emergent tracheotomy or rigid bronchoscopy is needed. Having the patient awake during fiberoptic induction may be helpful when severe tracheal compression is noted, as well as intubation with a small diameter endotracheal tube.[89] Ideally, an endotracheal nerve-monitoring tube would be inserted, but the outer diameter tends to be larger and may pose difficulty during intubation in cases with severe tracheal compression. Consideration can be made for staging the procedure if there is any concern for the functional status of the RLN during resection.

Most substernal goiters are found in the anterior mediastinum, and less frequently in the posterior mediastinum.[62] A CT scan of the neck and chest with contrast should be done to help delineate the extent and the blood supply and for surgical planning. Generally, the blood supply to the substernal thyroid gland originates in the neck and can be readily controlled in this area. Hemostasis can be obtained by control of the superior and inferior thyroid arteries; hence, removal through the neck with a transcervical incision can be an option. Only rarely does an intrathoracic goiter receive its blood supply from mediastinal vessels; however, such a finding favors a developmental cause. In this case, a sternotomy is anticipated, particularly if the goiter extends below the aortic arch. When in doubt, a multidisciplinary approach should be coordinated with preoperative consultation involving thoracic and vascular surgery.[62] Video-assisted thoracoscopic surgery can also be used to mobilize the mediastinal portion of the substernal goiter and aid in its removal in selected cases.[36]

KEY POINTS

- The surgical procedure of choice for a thyroglossal duct cyst is the Sistrunk procedure. A lingual thyroid is the most common site for functioning ectopic thyroid tissue, and has a 1% chance of harboring malignancy.

THYROID CANCER AND THE SURGICAL MANAGEMENT

The incidence of thyroid cancer in the United States and worldwide has increased 300% over the past three decades, due predominantly to an increase in PTC.[63,64] Differentiated thyroid cancer, arising from thyroid follicular cells, includes PTC, follicular thyroid cancer (FTC), and Hurthle cell cancer (HCC). Of the differentiated cancers, PTC comprises approximately 85% to 90% of cases compared with 12% with follicular histology; less frequent is HCC, and even less common is poorly differentiated cancer. PTC has the best prognosis, with an estimated 5-year survival rate of 98.1% overall, 99.9% for localized disease, and 55.5% for distant disease.[64] Recurrence, metastases, and death may occur in 10% to 15% of patients with more aggressive variants of PTC, such as tall cell variant, columnar cell variant, and hobnail variant,[26] whereas a diagnosis of anaplastic thyroid cancer (ATC) tends to be grim.

Papillary Thyroid Cancer

The surgical treatment of PTC is best divided into two groups based on the size, clinical characteristics, and aggressiveness of these lesions: papillary microcarcinoma (PMC) and standard PTC.

Papillary Microcarcinoma. PMC refers to a small papillary cancer, less than 1 cm in diameter. PMC does not show invasion through the thyroid capsule, is not associated with lymph node metastases, and tends to be found in a young person as an occult lesion when thyroidectomy has been performed for another benign condition, or incidentally on high-resolution ultrasound. The options for very low–risk disease are active surveillance (AS) of the lesion with close clinical and sonographic follow-up or thyroid lobectomy. The rationale for offering AS is related to the indolence of PTC, as demonstrated by two landmark clinical trials that reported similar outcomes in patients with biopsy-proven PMC that was not surgically removed and were followed for up to 15 years.[65,66]

Standard Treatment of Most Papillary Carcinomas. The American Thyroid Association (ATA) guidelines outline that surgery is the standard of care for most PTCs greater than 1 cm.[26] The most recent 2015 ATA guidelines have changed the way we approach low-risk thyroid cancer and the extent of surgery patients are offered. Well-differentiated thyroid cancer (WDTC) that is unilateral, is less than 4 cm in size, and has no high-risk features can be managed with lobectomy alone.[26] Additional low-risk features include the absence of aggressive histology (hobnail variant, tall cell variant, columnar cell carcinoma), and no evidence of vascular invasion.[26] Intermediate-risk disease has microscopic invasion into the perithyroidal soft tissue, aggressive histology, vascular invasion, and clinical N1 disease with more than five positive lymph nodes (<3 cm in largest dimension).[26] High-risk disease has gross extrathyroidal extension into the surrounding tissue, incomplete tumor resection, distant metastases, and N1 disease with lymph nodes greater than 3 cm in the largest dimension.[26] Universal total thyroidectomy followed by RAI is no longer the standard approach for all PTCs. The best treatment for PTC is more nuanced and may include lobectomy or total thyroidectomy, with appropriate CND or lateral neck dissection (LND) when nodes are involved or whether RAI therapy is required postoperatively.[26] For high-risk disease, bilateral thyroid resection improves survival and reduces recurrence rates compared with unilateral resection,[26] whereas low-risk disease can often be treated with lobectomy alone.[26]

Follicular Thyroid Cancer

FTC is classified under the umbrella of WDTC and is derived from follicular epithelium. According to the Surveillance, Epidemiology, and End Results Program (SEER) data, the 1980 to 2009 FTC incidence was 1.19 per 100,000 woman-years and 0.55 per 100,000 man-years.[67] This is much lower than the incidence of PTC, at 9.21 per 100,000 woman-years and 3.10 per 100,000 man-years.[67]

FTC differs considerably from PTC in terms of epidemiological, cytological, and ultrasound features, as well as clinical behavior. FTC is less common than PTC, patients tend to present at an older age, and it is more common in females (3:1).[67] Tumor multicentricity and local lymph node spread are less common than in PTC. Metastatic spread of tumor occurs by hematogenous dissemination to the lungs, bones, and other peripheral tissues, compared with the lymphatic spread seen in PTC.

For patients with minimally invasive FTC (which includes tumors with invasion of only the capsule of the tumor without vascular invasion), ipsilateral lobectomy is sufficient.[26,68] However, for most patients with invasive FTC with gross capsular invasion (with or without surrounding soft tissue invasion) or vascular invasion (fewer than four foci present is minimally invasive, and more than four foci present is extensive vascular invasion), the ideal operation is like that for PTC, although the rationale for its performance differs.[26,68] Near-total or total thyroidectomy should be performed, not because of multicentricity but rather to facilitate later treatment of metastatic disease with RAI.[69] Remnants of normal thyroid in the neck are ablated by RAI, and if peripheral metastases are detected they should be treated with high-dose RAI therapy. Although lymph node metastases in the lateral region of the neck are not commonly found, a unilateral CND and a selective LND should be performed if metastatic nodes are identified.

Finally, all patients with papillary or follicular cancer should be treated for life with levothyroxine therapy in sufficient doses to suppress TSH to the appropriate level.[69] Careful follow-up is required to monitor for cardiac or other problems, such as osteoporosis from thyrotoxicosis.

Noninvasive Follicular Thyroid Neoplasm with Papillary-Like Nuclear Features

Noninvasive follicular thyroid neoplasm with papillary-like nuclear features (NIFTP) is a diagnosis that can only be made on surgical pathology, and not on FNA cytology. When thyroid lobectomy is performed, and the result is NIFTP, no further surgery or postoperative treatment is required. In a case series, Rosario et al. reported no evidence of recurrence after 1 to 10 years of follow-up among patients who received lobectomy for tumors greater than 1 cm.[70] The literature demonstrates that, when NIFTP is diagnosed, less than 1% of tumors will recur within the first 15 years, whereas most differentiated carcinomas are at risk of relapsing within the first decade after initial therapy.[42] Thus, no further surgery is indicated. The diagnosis of NIFTP is an important one to make, as it can alleviate the psychological impact of having a cancer diagnosis and can save the healthcare system thousands of dollars per patient ($5000 to $8500 per patient in the United States) by avoiding unnecessary treatment with RAI.[71]

Hurthle Cell Thyroid Cancer

Hurthle cell tumors were once thought to be variants of follicular neoplasms; however, the most recent edition of the World Health Organization classification of tumors designates HCC and FTC as separate entities.[72] Although the incidence of thyroid cancer, namely PTC, is on the rise, the rates of HCC have remained stable and represent approximately 5% of differentiated thyroid carcinomas.[72]

Hurthle cell tumors tend to behave more aggressively, have a higher rate of locoregional recurrence, and are more difficult to treat than the usual follicular neoplasms for several reasons: 1) the incidence of carcinoma varies from 5.3% to 62% in different clinical series; 2) benign-appearing tumors can later metastasize in up to 2.5% of patients; and 3) HCCs are far less likely to concentrate RAI than are the usual follicular carcinomas, which makes treatment of metastatic disease difficult. Given the heterogeneity and unpredictability in presentation and prognosis, the best treatment approach remains controversial. Our group typically advocates a more aggressive surgical approach, including total thyroidectomy with or without compartmental lymphadenectomy.[26,73]

Medullary Thyroid Cancer

Medullary thyroid cancer (MTC) accounts for 5% to 8% of all thyroid cancers. It is a C-cell, calcitonin-producing tumor that contains amyloid or an amyloid-like substance, as well as other peptides and amines such as carcinoembryonic antigen, serotonin, neurotensin, and a high-molecular weight adrenocorticotropic hormone-like peptide. These substances may result in a carcinoid-like syndrome with diarrhea or Cushing syndrome, especially when widely metastatic tumor is present. MTC spreads to the lymph nodes of the neck and mediastinum and later disseminates to the lungs, liver, and elsewhere. The tumor is radioresistant, does not take up RAI, and is not responsive to thyroid hormone suppression. Hence, a thorough surgical approach is mandatory.

Most MTC of the thyroid is sporadic (approximately 75%), but it can also be transmitted in a familial pattern in 25% of cases. This tumor or its precursor, C-cell hyperplasia, occurs as a part of multiple endocrine neoplasia type 2A (MEN2A) and type 2B (MEN2B) syndromes or, more rarely, as part of familial MTC syndrome (see Table 82.2).[74] MEN2 syndromes are transmitted in an autosomal dominant manner caused by mutations of the *RET* oncogene on chromosome 10.[75] All patients with MTC should be screened for hyperparathyroidism and pheochromocytoma.[75] The risk of these two disease states accompanying MTC in MEN2A is greatest in patients with a 630 or 634 *RET* mutation.[75] Family members, especially children, of a patient with MTC of the thyroid should also be screened for MTC if the patient has MEN2 with a *RET* oncogene mutation, but also if the tumor is bilateral or if C-cell hyperplasia is present.[76]

The standard treatment for patients with MTC is a total thyroidectomy with a prophylactic CND. LND is dictated by the presence of biopsy-proven disease in the lateral neck. A thorough surgical approach is paramount to achieving a cure. Recent evidence shows that preoperative calcitonin values can help determine the extent of lymph node dissection.[77] The risk of lymph node metastases is low when calcitonin levels are less than 20 pg/mL (the normal reference range is <10 pg/mL).[77,78] Calcitonin levels higher than 20 pg/mL, 50 pg/mL, 200 pg/mL, and 500 pg/mL are associated with the presence of lymph node metastases in the ipsilateral central and ipsilateral lateral neck, in the contralateral central neck, in the contralateral lateral neck, and in the upper mediastinum, respectively.[77,78]

Prevention of the development of MTC is best achieved by prophylactic thyroidectomy in young children who are found by genetic screening to have a mutated *RET* oncogene. Further reading of a comprehensive set of revised guidelines regarding diagnosis, screening, surgical, and medical treatment, follow-up of MEN2A and 2B, their pheochromocytomas, and hyperparathyroidism, as well as sporadic medullary cancer, is recommended for greater depth on the topic.[79]

Generally, patients with MEN2A syndrome have a better prognosis than do those with a sporadic tumor, whereas patients with MEN2B syndrome have the most aggressive tumors and rarely survive to middle age.[79] In children with MEN2B, screening for *RET* oncogene mutation should be done after birth, and with a mutated *RET* oncogene, total thyroidectomy should be done as early as possible within the first year of life in a tertiary care setting.[79] In MEN2B patients or infants and children older than 1 year of age, a prophylactic level VI neck dissection should be considered as well.[79] A multidisciplinary approach is recommended, with involvement of genetic counseling.

TABLE 82.2 Inherited Subtypes of Medullary Thyroid Cancer (RET oncogene)

MEN2A (*RET* oncogene)	MEN2B (*RET* oncogene)	Familial medullary thyroid cancer syndrome
Medullary carcinoma	Medullary carcinoma	Medullary thyroid carcinoma
Pheochromocytoma	Pheochromocytoma	Variant of MEN2A
Hyperparathyroidism	Hyperparathyroidism - unlikely	
	Ganglioneuroma phenotype	
	Mucosal neuromas	

Patients with recurrent or persistent MTC who may not be candidates for surgery may be eligible for new chemotherapeutic modalities like vandetanib or selpercatinib. A recent trial in patients with previously treated *RET*-mutant MTC showed a promising antitumor response with selpercatinib, whether or not they received previous first-line therapy with vandetanib, cabozantinib, or both[80] (Table 82.2).

Anaplastic Thyroid Cancer

ATC is a rare and lethal form of thyroid cancer that is initially derived from a differentiated tumor such as PTC or FTC. However, over time, ATC accumulates a series of mutations, making it a more undifferentiated phenotype and one of the most aggressive of all cancers in humans. It comprises 1.3% to 9.8% of all thyroid cancers globally.[81] In contrast to other WDTCs, anaplastic cancers are extremely aggressive, with a disease-specific mortality rate approaching 100%. The tumor grows rapidly, with a median survival of 5 to 6 months and a 1-year survival rate of 20%.[36,81] Often, ATC presents at an advanced stage, with symptoms of airway obstruction and vocal cord paralysis on initial evaluation. Up to 46% of newly diagnosed patients present with widely metastatic disease at diagnosis, and up to 90% of patients have invasion to the surrounding soft tissue.[36] Thus, surgical cure is unlikely with ATC, and patients will only benefit from palliative measures, no matter how aggressively surgery is pursued.

For ATC, it is paramount that an efficient multidisciplinary approach is coordinated. Flexible nasopharyngoscopy should be performed for airway assessment, as well as urgent imaging (CT with contrast, with or without MRI), with potential panendoscopy and bronchoscopy to assess for local soft tissue invasion of the trachea, esophagus, and potential distant metastases to the chest or abdomen.[82] A PET-CT scan is also necessary for identifying local and distant metastases. An FNA, core biopsy, or open biopsy is essential for making the diagnosis and to avoid confusion with other entities such as lymphoma. Tracheostomy should generally be avoided in patients with ATC.

Despite the advanced stage in presentation of ATC, there is optimism, with novel immunotherapies that have demonstrated improved outcomes and quality of life for these patients.[83] One group recently reported a *BRAF*-mutated ATC patient with end-stage, locally advanced, unresectable ATC who was effectively treated with combination therapy with dabrafenib (a selective BRAF inhibitor), trametinib (a selective MEK inhibitor), and pembrolizumab. Following induction of therapy with this three-drug combination, the tumor shrunk significantly, allowing for complete surgical resection and chemoradiation with prolonged survival.[83] Large clinical trials are in progress; however, this case report represents a promising treatment modality for *BRAF*-mutated ATC.

Radioactive Iodine Therapy

After surgery for WDTC, RAI therapy with ^{131}I is commonly used in order to ablate any remaining normal thyroid remnant present in the thyroid bed, as adjuvant therapy (to destroy suspected but unproven metastatic disease), or to target known persistent disease.[84] However, it is paramount to achieve complete surgical resection of macroscopic disease rather than relying on RAI to postoperatively "mop up" unresected residual disease for WDTC.

Contrary to previous practice, RAI ablation is more selectively being used postsurgery, especially in low-risk patients. RAI does not tend to be as beneficial in low-risk patients with PMC or in patients with WDTC 1 to 4 cm in size and no other worrisome features.[84] As more evidence emerges, there has been an increasing shift away from the routine use of RAI in low- to intermediate-risk patients and for selective use based on interoperative findings, imaging, and pathology. Even the dose of RAI has been questioned, leading the ATA guidelines to recommend use of a lower dose of RAI in low- and intermediate-risk disease.[26,85] Studies have shown that the use of high-dose RAI (i.e., 100 mCi) has no advantage for remnant ablation over a lower dose of 30 to 50 mCi for low- to intermediate-risk disease and is associated with greater side effects.[84,86]

KEY POINTS

- Active Surveillance can be offered to patients with very low-risk papillary microcarcinoma. Thyroid Lobectomy is an option for well-differentiated thyroid cancer that is unilateral, less than 4 cm in size with no evidence of high-risk features. Follicular and Medullary thyroid cancer are approached with more aggressive surgical intervention.

INDICATIONS FOR SURGERY OF THE THYROID GLAND

Indications for Lobectomy versus Total Thyroidectomy

The indications for lobectomy and total thyroidectomy are derived from the recommendations of the ATA guidelines.[26]

The indications for lobectomy include:

a. Low-risk PTC (WDTC <2 cm, no extrathyroidal invasion, no locoregional metastases, and lack of aggressive histology or aggressive genetic markers)
b. Unifocal WDTC less than 4 cm with no other locoregional disease or clinical risk factors (family history of thyroid cancer, or history of radiotherapy to the head and neck)
c. Benign symptomatic thyroid disease with single-lobe pathology, i.e., compressive symptoms
d. Diagnostic purposes (i.e., follicular neoplasm or undetermined pathology on FNA).

The indications for total thyroidectomy include:

e. Unifocal disease greater than 4 cm, or malignant disease in bilateral lobes
f. Need for postoperative surveillance (with Tg) or further treatments (with RAI) requiring complete excision of thyroid gland
g. Locoregional or metastatic disease
h. Benign symptomatic disease such as Graves disease refractory to medical management, or compression along TEG or major vasculature
i. If the patient has a less than 4-cm malignancy that is considered low-risk and wishes to have a near-total or total thyroidectomy, so they are completely cured of their disease and undergo one operation instead of two, the guidelines endorse this approach.

Indications for Active Surveillance

AS for low-risk WDTC is an alternative to immediate surgical resection for patients with PMC (<1 cm), or indolent disease less than 2 cm. AS of a malignancy involves close follow-up both diagnostically and clinically, in lieu of immediate surgery, with the intention of treatment with curative intent if the disease progresses or if the patient wishes to have surgery.[92] Even though the data for AS demonstrate a safe and effective alternative, most patients would prefer to have surgical resection.[26,65,87] However, not all patients are eligible for surgery, and in the right setting, AS is a reasonable option.

Indications for Remote Access Surgery

While the transcervical approach has excellent safety, neck scarring at the incision site may have a detrimental effect on quality of life. Though most patients are satisfied with the appearance of their postthyroidectomy scar, many younger patients report feeling self-conscious of their scar.[104-106] Furthermore, while most patients experience adequate wound healing, patients with darker skin are significantly more likely to develop keloids or hypertrophic scars. Improved cosmesis was therefore the principal motivation for the development of remote-access techniques for thyroidectomy, with the intention of avoiding a visible scar and ultimately creating "scarless" surgery.

Indications for Prophylactic Central Neck Dissection

For low-risk and intermediate-risk patients with small (T1 or T2), noninvasive, cN0 disease, generally a prophylactic CND is not done unless there is aggressive PTC histology, such as that presented by tall cell, diffuse sclerosing, and insular variants.[15,26] Prophylactic CND may increase the risk of permanent hypoparathyroidism and confer little to no survival advantage to the patient or improvement in long-term outcome.[15,28,88] However, for patients with advanced primary tumors (T3 or T4) or risk factors that may increase the risk of recurrence (such as older or very young age, larger tumor size, multifocal disease, extrathyroidal extension, or known lateral neck metastases) or recommendations by the multidisciplinary team, a prophylactic CND may be considered.[15,26,28]

There is a role for bilateral prophylactic CND with total thyroidectomy in MTC, given the high risk for metastasis in the central neck at the time of presentation, according to the National Comprehensive Cancer Network guidelines and the ATA guidelines.[90,91]

Indications for Therapeutic Central Neck Dissection

The role for therapeutic CND (levels VI and VII) in suspected or biopsy-proven nodal disease (cN1) is well accepted.[26] A distinction should be made from microscopic central nodal disease, which does not carry the same recurrence risk as macroscopic clinically detectable disease.[93] Once lymph node involvement is noted in the lateral neck, over 80% of patients have involvement in the paratracheal region.[15] Thus, therapeutic CND should accompany total thyroidectomy when macroscopic disease is present, either ipsilaterally or bilaterally. A CND can be bilateral or unilateral and refers to comprehensive removal of the pretracheal and prelaryngeal lymph nodes, along with at least one paratracheal nodal basin.[15] Generally, a unilateral CND is preferred when the disease is confined to one paratracheal region, to minimize the risk to bilateral RLNs and parathyroid glands.

Indications for Lateral Neck Dissection

There is a role for therapeutic LND in biopsy-proven nodal disease; however, routine prophylactic LND has not been proven to improve survival.[23] Therapeutic surgical resection of the lateral neck can reduce the rate of recurrence and mortality.[23] Two studies of the large SEER database found a poorer overall survival in patients with follicular carcinoma and PTC over age 45 years, with cervical lymph node metastases or distant metastases, and with larger tumor size.[26,93]

Lateral neck lymph node involvement occurs in up to 40% of patients with thyroid cancer.[26] When macroscopic disease is involved with metastatic differentiated thyroid cancer, the procedure of choice is a selective neck dissection, and rarely is a modified radical neck dissection required. A selective neck dissection involves removal of less than all five nodal levels and is directed by the patterns of lymphatic drainage from the primary tumor, with preservation of the IJV, cranial nerve (CN) XI, and SCM,[23] whereas a modified radical neck dissection describes comprehensive removal of nodal metastases from level I to V, with preservation of one or more of the following nonlymphatic structures: IJV, CN XI, and SCM.[23]

Cervical metastases to the lateral neck compartment generally occur after central neck involvement, and commonly to levels II to V.[23,26] If macroscopic metastases are present, a selective neck dissection of levels IIa, III, IV, and Vb should be performed.[23] Rarely, the submental nodes (level I) are involved in metastatic thyroid cancer. Thus, unless evidence of macroscopic disease is present clinically or on imaging, routine dissection of levels I, IIb, and Va is not recommended.[23] Level Va is only necessary when US evaluation shows suspicious nodes in level V, as there is risk to injury of the accessory nerve with elective dissection of this compartment.[23] Similarly, level 2b resection is required if nodal disease exists in level 2a.[23] While uncommon, skip metastasis to the lateral neck can occur without evidence of central neck disease on imaging or clinical examination. It is important, however, that if lateral neck compartment dissection is considered, the ipsilateral central neck is also considered.[41]

KEY POINTS

- Therapeutic central neck dissection should accompany total thyroidectomy when macroscopic disease is present, either ipsilaterally or bilaterally. Routine prophylactic lateral neck dissection has not proven to improve survival. However, there is a role for therapeutic lateral neck dissection in biopsy-proven nodal disease.

TRANSORAL APPROACH TO THYROIDECTOMY

Although remote-access techniques have become a popular alternative to the transcervical approach to thyroidectomy in Asia, where many of these techniques were pioneered, they have not yet achieved widespread adoption in the United States.[107,108] This trend may shift with the popularization of the transoral endoscopic thyroidectomy vestibular approach (TOETVA), given its favorable outcomes both in Asian and North American cohorts.[108-110]

The early remote-access techniques, such as the anterior breast approach[111] and the axillary approach,[112] evolved to the axillo-breast approach,[113] which offered cosmesis and a low rate of complications but was technically challenging. The postauricular "facelift" approach sought to improve the technical challenges by relying on familiar dissection planes that are used in parotidectomy.[114,115] This approach offered a shorter distance to the thyroid and good postoperative cosmesis; however, the narrow working space impedes exposure of the contralateral thyroid lobe, meaning a second, contralateral postauricular incision is often necessary for total thyroidectomy.[116]

While the aforementioned remote-access techniques have demonstrated good cosmesis and outcomes, their operative difficulty, long routes to the central neck, extensive dissection, and unfamiliar dissection planes have slowed their adoption.[117] With the aim of developing a more minimally invasive approach, transoral thyroidectomy was experimentally performed via sublingual as well as combined sublingual and vestibular access in human cadavers and porcine models.[118,119] A significant risk of the sublingual approach is injury to the hypoglossal and sublingual nerves. To avoid this risk and the restricted freedom of movement through the sublingual port, Richmon et al. developed a transoral approach using three vestibular ports and the da Vinci robot without an incision through the floor of the mouth.[120] Three gingival-buccal incisions are made, at midline and on either side laterally, and carbon dioxide insufflation maintains a working cavity. This transoral vestibular approach offers superior visibility of the central compartment of the neck and, in contrast to other remote-access approaches, provides midline access to the thyroid.

In 2016, Anuwong et al. demonstrated success in performing this approach with conventional laparoscopic instruments and an ultrasonic device. This initial experience of TOETVA had median operative time of 115.5 minutes (range 75–300 minutes). Outcomes were comparable to conventional open thyroidectomy, with minimal complications. Out of 60 procedures, there were two cases of transient RLN injury and three cases of transient hypoparathyroidism. One patient had hematoma occurring 3 days postoperatively. No patients had permanent RLN injury or hypoparathyroidism.[109] Early experience with TOETVA in North America demonstrated similarly good outcomes.[110] Since these early reports, TOETVA has enjoyed widespread adoption globally.[121] To date, the largest North American series comparing TOETVA with the transcervical approach demonstrates similar safety and efficacy regardless of body mass index, with no difference in RLN injury, hypoparathyroidism, seroma, infection, or hematoma.[122]

More recently, transoral thyroidectomy using a robotic system has been explored. In 2018, Razavi et al. reported early experiences with transoral robotic thyroidectomy vestibular approach (TORTVA) using the da Vinci robot and three vestibular ports as initially described by Richmon et al. Comparing seven cases of TORTVA to 20 cases of TOETVA, Razavi et al. found comparable outcomes overall; however, the median operative time was significantly longer for TORTVA (322 vs. 188 min).[123] Similar to TOETVA, transoral robotic thyroidectomy (TORT) utilizes three vestibular incisions, but with an additional unilateral axillary incision for introduction of a trocar to produce countertraction. In their series of 24 cases of TORT, Kim et al. reported a mean operative time of 232 minutes. In three cases, there was permanent mental nerve injury; however, no other complications were reported.[124]

KEY POINTS

- Remote access techniques, such as transoral endoscopic thyroidectomy vestibular approach (TOETVA) demonstrates similar safety and efficacy to the open transcervical approach regardless of body mass index, with no difference in RLN injury, hypoparathyroidism, seroma, infection or hematoma.

OPEN SURGICAL TECHNIQUES

Lobectomy and Total Thyroidectomy

The descriptions of the surgical techniques outlined below are based on the principles employed by the authors at our institution.

In a patient with thyroid carcinoma undergoing a total thyroidectomy, the surgeon should approach the side of concern first, where the largest nodule with a presumed cancer diagnosis is present. Frozen section review of the index thyroid nodule by pathologists is typically unreliable for Bethesda stage 3 and stage 4 lesions and should not be utilized in most cases of thyroid pathology. The goal is to completely resect the pathology in question while protecting important structures, including the RLN and the parathyroid glands on the contralateral (uninvolved) side.

Intraoperative nerve monitoring is often used to assess the integrity of the RLN. It is important to maintain a stable vagal nerve and RLN stimulus throughout the case in order to assure adequate vocal fold function postoperatively. If the signal is weakened intraoperatively, the patient should be counseled preoperatively that staging the procedure is a possibility to prevent the need for tracheostomy. Tracheostomy in this patient population is not without risk, due to the potential for a large mediastinal space and exposure of the innominate artery. In cases where gross nerve integrity has been confirmed but physiologic activity is not noted, staging the contralateral thyroidectomy or CND may be appropriate.

An open thyroidectomy involves a patient placed in supine position with the neck extended. A transcervical incision is made approximately two fingerbreadths superior to the clavicle, within a normal skin crease on the neck for cosmesis. A 3- to 5-cm midline low collar incision is made and carried down through the subcutaneous tissue and platysma muscle, down to the strap musculature (the sternohyoid, sternothyroid, and thyrohyoid). The superior and inferior skin flaps are raised, and the strap muscles are divided along the midline raphe vertically before retracting them laterally to expose each thyroid lobe. The thyroid lobe of interest is dissected first, and blunt instrumentation with or without cautery is used to laterally retract the sternothyroid and sternohyoid musculature away from the thyroid fascia. Once the strap muscles are retracted, the thyroid lobe is bluntly dissected while staying close to the thyroid capsule and within the fascia plane to reduce the risks of inadvertent injury of surrounding structures. The thyroid at the inferior trachea is dissected at midline, in order to identify the trachea as well as to mobilize the lobe inferiorly over the trachea, and then superiorly to dissect the pyramidal lobe and Delphian nodes. The superior pole of the lobe is dissected and mobilized, including the adjacent cricothyroid and inferior constrictor muscle, where the trajectory of the EBSLN can be identified in 85% of cases.[95] The superior pole vessels are ligated adjacent to the thyroid lobe, rather than cephalad to it, to prevent damage to EBSLN. We identify the RLN at the mid thyroid lobe region and then proceed to dissect superiorly (anterograde) toward the nerve insertion point at the cricothyroid region, which serves as a stable landmark. The intraoperative nerve monitor is used as a guide and is meant to help the surgeon confirm and protect the RLN if any question regarding the anatomy or bleeding is encountered. We can also identify the ITA, which courses perpendicular to the nerve. Rather than ablate the artery, we tend to dissect bluntly deep to the ITA to identify the RLN. Once the parathyroid glands are isolated, this also allows for mapping of the RLN, as the superior parathyroid lies deep to the nerve, and the inferior parathyroid superficial to it. Often, a fat pad is identified first and preserved, as it is intimately associated with the parathyroid gland. Additionally, care is taken to leave an adequate blood supply to the parathyroid glands while moving the gland off the thyroid lobe. Once the RLN is preserved, the final step is to mobilize the thyroid off BL medially and rotate the gland over the trachea.

We are careful to identify any intracapsular parathyroid glands that may have been adherent to the thyroid capsule during dissection and/or whose vascular supply was from the thyroid gland itself. If intracapsular dissection of the parathyroid gland off the thyroid capsule was required, and the blood supply is compromised, then the parathyroid gland is placed in normal saline on ice for later autoreimplantation, once frozen section confirmation has been made that it is indeed parathyroid tissue. These glands, if spliced and minced, can be reimplanted into the rich vascular supply of the accessible, adjacent neck musculature, such as the SCM or strap muscle. Any parathyroid gland that appears devascularized can undergo autoreimplantation, particularly if there is concern with the integrity of the other three parathyroid glands during surgery. Generally, once the parathyroid gland reestablishes its new blood supply, the secretory function of the gland is preserved, and PTH function is maintained, depending on the presence of benign or malignant disease.[96]

In a total thyroidectomy, the contralateral lobe is dissected in a similar fashion. It is important to confirm RLN functioning on the ipsilateral side prior to moving to the contralateral lobe to avoid potential bilateral vocal cord immobility and the requirement for a tracheostomy. If weakness of the RLN is noted intraoperatively, staging the remaining lobectomy until RLN recovery is a reasonable option. A near-total thyroidectomy means that a very small amount of thyroid tissue is left on the contralateral side of the cancer to protect the parathyroid glands and RLN. The ultimate goal for the surgeon is completeness of resection, as residual tissue can affect Tg levels during follow-up, as well as the success of radioactive ablation. Just before closing the wound, careful hemostasis and visualization of important anatomic structures are mandatory for success. Some surgeons use energy devices to help with hemostasis, but this is based on surgeon preference and availability of hospital resources.

When closing the wound, the fascia of the strap musculature is reapproximated, leaving a space inferiorly for potential drainage. Surgical drains are not necessary in most cases, but may be used if a large amount of dead space is present. After verifying the absence of any further bleeding, the skin is closed with 3-0 vicryl subdermal sutures. Surgeon preference is the deciding factor for whether stitches or glue alone are used in skin closure. Stitches can be placed in a subcuticular fashion underneath the skin for closure of the wound, and/or tissue adhesive glue may be placed over the skin after everting the edges meticulously for final wound closure.

Retrograde Medial Approach to the Thyroid Dissection

Most often, surgeons approach the RLN through lateral dissection of the thyroid; however, a medial approach can be advantageous in cases with a nonrecurrent RLN, large tubercle of Zuckerkandl, extrathyroidal extension of cancer along the distal RLN segment (with exception of cricothyroid junction involvement), or large goiters.[8] Some of the advantages of this approach include early identification of the RLN, with no thyroid tissue left unresected at the cricothyroid junction.[8] If the tumor is in the isthmus and there is a concern of tumor spillage, then a lateral approach to the thyroid is advised.

Central Neck Dissection

The central neck compartment (levels VI and VII) can be accessed through the thyroidectomy incision. Once the thyroid gland has been exposed, and the carotid sheath contents have been lateralized, we begin by dissecting over the carotid artery inferiorly to the level of the innominate artery and superiorly to the level of the cricoid on the respective side. After identification of the RLN, careful dissection continues along the nerve, removing fibrofatty tissue between the course of the nerve and the trachea. On the right-hand side, lymph node tissue lies both superficial and deep to the nerve, and therefore the right RLN should be transposed for the fibrofatty tissue to be resected medially to the trachea. The posterior boundary of the compartment is the esophageal muscularis, and it is important to clean all fibrofatty tissue off this structure. In the rare case of invasive disease, the muscularis itself can be removed carefully to avoid creating a perforation through the underlying mucosa. The preoperative placement of a Maloney dilator or gastric tube may facilitate identification of the esophagus. Esophageal defects should be closed primarily while inverting the mucosa, such as with a Connell technique. The superior extent of the dissection leads to the ITA, the trunk which gives off blood supply to the superior parathyroid gland. Preservation of this trunk is paramount in order to preserve the vascular integrity to the superior parathyroid tissue. It is expected that the inferior parathyroid glands will be devascularized and likely removed during a central compartment resection, given the unpredictable location of the inferior glands compared to the superior parathyroid glands.[23] As such, they should be identified early if possible. If the parathyroid tissue is inadvertently removed, it can be clipped and removed from the final specimen and then reimplanted at the end of the case. Parathyroid tissue can be stored on sterile ice until the time of reimplantation. Due to the risk of hypoparathyroidism from central compartment resection and the inherent difficulty with identification of these glands once the dissection has begun, one may choose to harvest these inferior glands prophylactically if they are identified early in the dissection for later reimplantation.

Lateral Neck Dissection

LND incorporates levels IIA through VB in patients with evidence of lateral neck disease in these compartments on preoperative evaluation. The incision for our LND is an extension of the thyroidectomy incision, approximately to the level of the mid-SCM. When possible, the incision is placed within a normal skin crease for cosmesis rather than curving the incision superiorly and against relaxed skin tension lines. If level IIB is involved, the incision may be extended higher with a more vertical direction in order to gain adequate exposure.

The subplatysmal planes are raised superiorly to one to two fingerbreadths below the angle of the mandible (to prevent injury to the marginal mandibular nerve) and inferiorly to the level of the clavicle. The subplatysmal fascia is incised at the inferior border of the submandibular gland, and we identify the digastric tunnel in order to follow it laterally to the IJV. We can then also identify the hypoglossal nerve just posterior to the digastric tendon. The SCM is then incised medially so that fibrofatty tissue is elevated medially. We identify level IIA by tracing out the accessory nerve in a lateral to medial trajectory towards the IJV. This defines the boundaries of levels IIA and IIB, and we then proceed to dissect down to the floor of the neck using a hemostatic scalpel blade or other dissecting instrumentation. Gentle retraction of the accessory nerve can help facilitate the level IIB dissection if necessary. Once this compartment has been cleared of disease, the dissection proceeds in an inferior direction along the medial edge of the SCM to dissect the compartments in level II to V. The contents of the floor of the neck, including the phrenic nerve, the brachial plexus (located in level IV), and the cervical rootlets, are protected during dissection. Next, we identify and skeletonize the omohyoid, which transverses in a diagonal direction at the level III–level IV junction. The exposure allows us to safely retract the omohyoid during the rest of the inferior dissection and expose the inferior aspect of level IV. The transverse cervical vessels are preserved, and, as we move medially toward the IJV, the thoracic duct is identified if we are on the left side of the neck and the lymphatic duct on the right side. An energy device, ties, or clips can be used to seal the lymphatic channels associated with the thoracic duct that are close to the IJV to prevent a potential chyle leak. Clips may make subsequent imaging and follow-up more difficult, and we generally avoid their use. Once the IJV is identified inferiorly, we elevate the fibrofatty tissue medially over the carotid artery, vagus nerve, and IJV. Once medialized, we stay over the anterior edge of the internal jugular and remove levels IIA/B, as well as excise the tissue over the strap musculature to cleanly resect our specimen *en bloc*. It is important to evaluate the retrocarotid location for any occult lymphadenopathy (much more common in thyroid carcinomas) and to dissect any fibrofatty tissue in level VB behind the SCM. If level VA is involved, dissection of the accessory nerve through the compartment from the SCM to the trapezius is completed. Although this may create traction on the accessory nerve, careful dissection and gentle retraction will protect the nerve and keep it intact. We perform a Valsalva at the end of the procedure in order to intraoperatively identify a chyle leak or bleeding from a major vessel. We stimulate all nerves for final confirmation of physiologic function, including the vagus, accessory nerve, hypoglossal nerve, and phrenic, and then proceed to close the neck. We place a single 7FR Blake drain into the lateral neck for every dissection, sutured to the skin. Subdermal closure is achieved using 3-0 vicryl interrupted sutures, and the skin can be closed with monocryl in a subcuticular fashion. Dermal glue can be placed over the incision.

MINIMALLY INVASIVE TECHNIQUES

Radiofrequency Ablation Technique

Image-guided thyroid ablation procedures can be performed using either thermal energy (RFA, laser ablation [LA], high-intensity focused ultrasound, and microwave ablation) or chemical methods such as ethanol instillation.[125] All ablative techniques cause coagulation necrosis to the desired nodule; however, each technique differs in the type of energy applied and how the tissue is targeted. Compared with other thermal ablation techniques, RFA and LA are accepted worldwide and have been found to be effective.[126-128] Our group is most familiar with RFA, which is an outpatient image-guided thermal ablative procedure that is a potential alternative to surgery for treating symptomatic benign nodules,[129-143] autonomously functioning thyroid nodules,[144-147] early primary thyroid cancer,[129,148-151] or recurrent thyroid cancer[129,152-155] that is not amenable to surgery. This approach is attractive, because it eliminates the need for a general anesthetic, an incision, or removal of the thyroid lobe at all. Compared with surgery, RFA takes significantly less time, costs less, and is associated with shorter hospitalizations.[148,156,157] After treatment with RFA, the size of a nodule is reduced over time by 33% to 58% after 1 month, by 51% to 85% after 6 months, and by 93% after 4 years.[150]

At the time of writing this chapter, the application of thermal ablative techniques is rapidly evolving and starting to infiltrate practices in North America.

KEY POINTS

- Thermal ablation is gaining traction worldwide as an alternative to surgery for treating symptomatic benign nodules, autonomously functioning thyroid nodules, early low risk primary thyroid cancer or recurrent thyroid cancer that is not amenable to surgery.

SURGICAL COMPLICATIONS

Recurrent Laryngeal Nerve Injury

Generally, the risk of injury to the RLN is low (temporary paralysis 9.8%, permanent 2.3%) in experienced hands, but can be variable depending on whether malignant or benign disease is present.[98,99] Furthermore, there is no evidence to suggest that the addition of a CND to a total thyroidectomy for thyroid cancer increases the permanent nerve injury rates when performed in a high-volume center.[162] However, in the presence of a NRLN, the chance of injury increases to 13%.[97] In-office ultrasound or preoperative axial imaging during the preoperative work-up of a thyroid nodule can help exclude an aberrant subclavian artery to anticipate a NRLN. Additionally, attempted early stimulation of the distal vagus nerve can alert the surgeon to the presence or absence of a NRLN: if the vagus nerve does not stimulate beyond the midpoint of the ipsilateral thyroid lobe, surgeons should suspect early branching of the RLN.

Unilateral RLN injury results in unilateral vocal fold paralysis with glottic insufficiency. The voice becomes breathy, and there is risk for aspiration of liquids, given incomplete glottic closure. Temporizing measures such as in-office injection laryngoplasty can help close the glottic gap if the injury is temporary. If RLN injury is permanent (lasts >9–12 months after onset of injury), then considerations are made for medialization thyroplasty, which medializes the paralyzed vocal fold permanently. Bilateral RLN injury is more worrisome and can lead to airway difficulty if both vocal folds assume a midline position, leading to a narrow glottic inlet. This may, in turn, lead to tracheostomy placement or measures to support breathing.

Hypoparathyroidism

The incidence of hypocalcemia due to parathyroid gland devascularization or removal after total thyroidectomy is 3% to 52% for transient and 0.4% to 13% for permanent postthyroidectomy hypocalcemia.[100,101] Because of their small size, delicate blood supply, and intimate anatomic position with the thyroid gland, parathyroid glands are at risk of accidental removal, trauma, or being devascularized during thyroidectomy.[102] If a parathyroid gland is recognized to be ischemic or nonviable, then it may be morselized and autotransplanted into the ipsilateral SCM. The rate of temporary hypoparathyroidism is much higher with CND, occurring in 14% to 40% of cases, with permanent hypoparathyroidism in 1.2%.[23,161,162]

Symptoms of hypocalcemia include circumoral numbness, tingling of the fingers and toes, and intense anxiety occurring soon after surgery. Chvostek's sign, which is carpopedal spasm, can appear early on physical exam. These symptoms occur with calcium levels of less than 7.5 to 8 mg/dL.

The diagnosis of postoperative hypoparathyroidism can be made in the early postoperative period (1–6 hours postoperatively) by checking PTH and serum calcium levels.[101] The pre- and postoperative trends can be tracked to determine the gradient difference in serum PTH and calcium.[101] If serum calcium levels are less than 8 mg/dL, oral calcium carbonate supplementation (with 500 mg–1 g of elemental calcium) of 1250 to 2500 mg four times per day with or without active vitamin D supplementation (calcitriol) is recommended. The addition of 1,25-dihydroxyvitamin D (calcitriol) is preferred, because it is the active metabolite of vitamin D and facilitates absorption of oral calcium. Patients with severe symptomatic hypocalcemia are treated in hospital with 1 g (10 mL) of 10% intravenous calcium gluconate immediately and infused over several minutes. Then, if necessary, 5 g of this calcium solution is added to 500 mL of intravenous saline to run continuously, at 30 mL/hour. Patients must be admitted for monitoring of serum calcium levels and for any cardiac QT abnormalities with electrocardiogram. Most often, postthyroidectomy hypocalcemia is transient, and intravenous calcium can be tapered and transitioned to oral therapy as patients become asymptomatic.

Spinal Accessory Nerve Injury

Injury to the eleventh CN is a complication of LND, particularly when level IIb or Va is dissected. Rarely is injury caused by transection of the nerve; rather, up to 20% of patients experience temporary or permanent injury from retraction or handling of the nerve during dissection.[158] Unfortunately, such an injury causes significant morbidity, such that patients experience a debilitating shoulder droop and are unable to raise their arm above their shoulder.[23] Some patients experience "shoulder syndrome," where shoulder movement is limited, painful, and disabling.[23]

Greater Auricular Nerve Injury and Sensory Cervical Rootlets

The most frequent permanent complication from LND, particularly of level II, is numbness of the lateral neck and ear.[23] With time, the area of numbness can reduce in size, but tends to be permanent around the ear lobe.[23]

Other Cranial Neuropathies

During LND, the marginal mandibular branch is at risk if dissecting level I and even the upper region of level II. This branch can lie low in the neck as part of the investing fascia of the submandibular gland.[23] Weakness is most often temporary, but can be permanent if transected, and results in an asymmetrical smile with difficulty drinking from a glass.[23]

Other less common injuries encountered during LND in the level III to level IV region include: phrenic nerve injury, brachial plexus injury, cervical sympathetic trunk injury, and thoracic duct injury.[23] Care should be taken while dissecting near the anterior and middle scalene muscles, as the phrenic nerve (which controls the diaphragm) lies on the scalene muscle deep to the carotid sheath. In between the anterior and middle scalene muscles is the entrance of the brachial plexus (which controls motor and sensory innervation to the upper extremity) into the neck, which is invested by the deep cervical fascia and is rarely injured during neck dissection. Injury to the cervical sympathetic nerves can result in Horner syndrome, characterized by ipsilateral ptosis, miosis, and anhidrosis.[159] Care should be taken when dissecting in the carotid sheath, as the sympathetic nerves can be found posterior to the carotid artery at the level of the C1 to C4 vertebrae.

Chyle Leak

Care should be taken when dissecting the lower lateral compartment of the neck to avoid inadvertent injury to the left thoracic duct and the right lymphatic duct. The left thoracic duct is larger than the right lymphatic duct and is responsible for lymph drainage from the entire body, except for the right sides of the head and neck. The right lymphatic duct drains the right side of the thorax and the right upper extremity.[103] The thoracic duct and lymphatic duct carry chyle and transport lymph back into the bloodstream. On the left side, the thoracic duct ascends into the superior mediastinum, which appears grossly as a lymph vessel that passes forward and laterally to drain into the left subclavian vein or the IJV. After dissection in this region, careful observation during a Valsalva maneuver is done to rule out a potential leak within this area so that a leak, if present, can be dealt with at the time of neck dissection.

Even though a chyle leak related to LND for thyroid carcinoma is uncommon, one series describes a chyle leak in 5.2% of patients intraoperatively and 8.3%of patients postoperatively.[103] A chyle leak should be treated appropriately, or it can lead to severe fluid and electrolyte imbalances. A low-output chyle leak (<500 mL/day) can be managed conservatively with fasting or a low-fat diet, whereas high-output leaks may also require octreotide therapy and possibly surgical ligation of the thoracic duct.[103]

Cosmesis

Cosmesis, or the appearance of the scar, after transcervical thyroid surgery is an important component that can influence a patient's quality of life. The authors' goal for cosmesis is to plan all incisions within a normal skin crease so the scar blends in with the natural skin lines. If the patient is known to develop hypertrophic scars and keloids or would like to avoid a neck scar altogether, transoral endoscopic thyroid surgery can be offered. For patients undergoing neck dissections for more extensive disease, the thyroid incision can be extended into the lateral neck crease in order to ensure good cosmesis.

Complications Associated with Transoral Surgery

There are complications associated with the transoral vestibular approach to thyroidectomy that may not be present with open surgery. Temporary or permanent (less likely) mental nerve injury occurs in

0% to 3.5% of cases, causing a sensory deficit in the lower lip and chin region. Other complications that can occur while developing the vestibular skin flap include temporary bruising or skin dimpling over the midline lower chin, perforation of the skin flap during vestibular dissection if not bluntly approached, and tearing of the inferior labial frenulum if there is excessive midline port movement. Rarely is a carbon dioxide embolism encountered; however, it is possible if there is venous injury or if excessive carbon dioxide insufflation pressure is used.[160]

Complications Associated with Radiofrequency Ablation

For treatment of benign nodules, the overall complication rate is 2.11% (95% confidence interval [CI]: 1.15–3.06), whereas the overall complication rate for recurrent thyroid cancers is higher, at 10.98% (95% CI: 4.82–17.15).[155] No life-threatening complications are reported, and minor complications include pain, skin burn, and hematoma.[129] The most common major complication noted is voice change, with an incidence of 0.94% for benign nodules, and there is an exceedingly low incidence of permanent changes.[155] Nodule rupture is the second most common major complication after RFA treatment (0.17%, 4/2421).[155] Patients may present with sudden neck bulging and pain at the RFA site due to delayed hemorrhage; however, the incidence remains low.

KEY POINTS

- The potential complications that occur with the open transcervical approach include infection, bleeding, scarring, temporary, or less commonly permanent RLN injury, hypoparathyroidism, or other cranial neuropathies (greater auricular nerve or spinal accessory nerve injury) if a lateral neck dissection is performed.

Conclusion, 1385

Since the 1970s, it has been known that serum thyroid hormone (TH) levels drop both during starvation and during illness. In mild illness, this involves only a decrease in serum triiodothyronine (T3) levels. However, as the severity and length of the illness increase there is a drop in both serum T3 and thyroxine (T4). This decrease of serum TH levels is seen in a variety of species and pathologies, including sepsis, myocardial infarction, and in fact probably any severe illness[1-3] (Table 83.1). The condition has been called the *euthyroid sick syndrome* or *sick euthyroid syndrome*. An alternative and probably more appropriate designation, which does not presume the metabolic status of the patient, is *nonthyroidal illness syndrome* (NTIS).

LOW TRIIODOTHYRONINE STATES

Food deprivation has profound effects on all levels of the hypothalamus–pituitary–thyroid (HPT) axis in a variety of species.[4] Starvation, and more precisely carbohydrate deprivation, appears to rapidly inhibit deiodination of T4 to T3 by type 1 iodothyronine deiodinase in the liver, thus inhibiting generation of T3 and preventing metabolism of reverse T3 (rT3).[5] This probably contributes to a drop in serum T3 and elevation of rT3. Because starvation induces a decrease in basal metabolic rate,[6] this decrease in TH levels has been interpreted as an adaptive response by the body to limit catabolism by inducing some degree of hypothyroidism. Likewise, a variety of illnesses induces decreased serum T3. Patients who exhibit only a drop in serum T3, which may occur during acute or mild disease, do not show clinical signs of hypothyroidism. Nor has it been shown that this decrease in serum T3 (in the absence of a drop in T4) has an adverse physiologic effect on the body.[1]

NONTHYROIDAL ILLNESS SYNDROME WITH LOW SERUM THYROXINE

As the severity of illness, and often associated starvation, progresses, there is the gradual development of a more extensive NTIS associated with low T3 and low T4 levels. Generally, thyroid-stimulating hormone (TSH) levels are low or normal despite the low serum hormone levels, and rT3 levels are normal or elevated. A large proportion of patients in an intensive care unit (ICU) setting have various degrees of NTIS, with low T3 and T4. A marked decrease in serum T3 and T4 in NTIS is associated with a high probability of death. For example, when serum T4 levels drop below 4 g/dL, the probability of death is approximately 50%, and with serum T4 levels below 2 g/dL, the probability of death reaches 80%.[7-9] Obviously, such associations do not prove a causal relationship, but they have certainly raised the consideration of TH treatment in the ICU setting.

Two major interpretations of NTIS can be found in the literature:

1. Although patients with NTIS are biochemically hypothyroid according to their serum levels, this reflects a physiologic response and does not exclude sufficient TH availability at the tissue level. Therefore, TH supplementation should not be considered in patients.
2. NTIS in patients with prolonged critical illness is a form of central hypothyroidism, and tissue hypothyroidism is present. As this is probably disadvantageous to the patient, therapy should be initiated if serum T4 levels are markedly decreased.

In this chapter, recent studies addressing changes at the tissue level during NTIS, as well as the mechanisms behind these changes, will be addressed. We will also summarize evidence for or against treatment of NTIS during prolonged critical illness and identify knowledge gaps that may guide the design of future clinical trials in this area.

TABLE 83.1 Illness-Induced Alterations in Serum Triiodothyronine (T3), Thyroxine (T4), Reverse Triiodothyronine (rT3), and Thyroid-Stimulating Hormone (TSH) in Various Species. ↓: decreased, ↑: increased, N: not affected, -: not reported.

Species	T3	T4	rT3	TSH	Ref
Human	↓↓	N or ↓	↑	N or ↓	(1)
Mouse	↓	↓↓	N or ↓	N	(11)(145)(32)

SERUM HORMONE LEVELS

Serum Total and Free Triiodothyronine

The majority of reports on NTIS indicate that total serum T3 levels are low.[10-13] Chopra and coworkers reported that free T3 levels were low[14] or, in a second report, often normal.[15] However, it is important to note that, in the second report, the patients with NTIS actually had average serum T4 levels that were above the normal mean and did not have significant NTIS. Sapin and coworkers compared free T3 levels found in patients with NTIS by direct dialysis, microchromatography, analog, two-step immune extraction, and a labeled antibody radioimmunoassay method.[16] Results were significantly below normal by five of the methods used and low in the most severe cases by one method. Faber and colleagues evaluated TH levels in 34 seriously ill patients, most of whom had low T4 and free T4 index values, and found generally normal free T3 and free T4 using an ultrafiltration technique.[17] A point to consider is that some ultrafiltration techniques fail to exclude TH-binding proteins from the filtrate and give spuriously high free hormone values.

Serum Reverse Triiodothyronine

Serum rT3 may be reduced, normal, or elevated during NTIS, and once elevated, rT3 does not increase much more in patients with more severe illness. Routine assessment of rT3 in patients with NTIS is not recommended, although it may help in distinct cases to differentiate between hypothyroidism and NTIS. Peeters and coworkers[18] found that in patients with NTIS, serum TSH, T4, T3, and the T3/rT3 ratio were lower, whereas serum rT3 was higher than in healthy subjects ($P < .0001$). Degradation of rT3 is reduced by decreased function of type 1 deiodinase, the enzyme that generates T3 and clears rT3. However, formation of rT3 is limited by the low level of substrate (T4) in serum and in tissues and perhaps by inhibition of T4 entry into cells. Thus, while it may be expected that rT3 should always be elevated, this is not the case, as it may be within the normal range. In contrast, starvation induces a fall in serum T3 and a rise in serum rT3 within 24 to 36 hours and a return to baseline upon refeeding.[5]

Serum Total and Free Thyroxine

Total serum T4 levels are reduced in NTIS in proportion to the severity and, probably, length of the illness.[10-12,15,19] In acute, short-term trauma such as cardiac bypass,[20] or in short-term starvation,[21] there is no drop in serum T4. However, with increasing severity and duration of trauma, illness, or infection, there is a drop in T4, which may become extreme. As indicated, serum T4 levels below 4 μg/dL are associated with a marked increased risk for death (up to 50%), and once T4 is below 2 μg/dL prognosis becomes extremely guarded. In neonates, low total T4 and TSH are associated with a greater risk for death and severe intraventricular hemorrhage. It has been suggested that TH supplementation might be a potential benefit in infants with the lowest T4 values.[13]

Total serum T4 is reduced, in part because of a reduction in thyroxine-binding globulin (TBG). A rapid drop in TBG to 60% of baseline within 12 hours after bypass surgery has been reported, possibly because of cleavage of TBG by protease, which causes TBG to lose its T4-binding activity.[22] Indeed, a cleaved form of TBG has been observed in the serum of patients with sepsis.[23] The impact of meningococcal sepsis on peripheral TH metabolism and binding proteins was studied in 69 children with meningococcal sepsis. All children had decreased total T3 and total T3/rT3 ratios, without elevated TSH. Lower total T4 levels were related to increased turnover of TBG by elastase. Thus, lowered TBG is a partial explanation for lower total T4 and T3 in NTIS.[24]

The results of free T4 assays in NTIS are method-dependent to some extent. Assays that include an estimate of TBG capacity to estimate free hormone typically return low values for calculated free T4 in NTIS. The free T4 level determined by dialysis varies widely, as does T4 measured by ultrafiltration[11-13,19,25]; the majority of reports are of normal or low values but, in some samples, elevated values.[11,12,26-28] Free fatty acids, if elevated to 2 to 5 mmol/L, can displace T4 binding to TBG and elevate free T4. Free fatty acids almost never reach such levels *in vivo*.[29,30] However, even small quantities of heparin (0.08 units/kg given intravenously, or 5000 units given subcutaneously), commonly given to patients in an ICU, can lead to *in vitro* generation of free fatty acids during extended serum dialysis and falsely augment apparent free hormone levels.[31] This is probably a widespread and serious problem, which explains many instances of apparently elevated free T4 levels in patients with acute illness. Of note, the subcutaneous administration of low molecular weight heparin was also reported to increase FT4 levels by up to 170% in specimens taken 2 to 6 hours after injection, leading to the advice to take specimens for FT4 estimation more than 10 hours postdose in patients receiving enoxaparin.[32] Results obtained using ultrafiltration compared with equilibrium dialysis are also variable but generally below the reference range. Thus, although free T4 is low in most assays that involve a correction for TBG levels, there is still some question as to the true free T4 in patients with NTIS. It is of interest that this problem does not carry over to estimates of free T3, which are depressed in most studies. There may be two reasons for this difference. Firstly, the depression of total T3 is proportionately greater than of total T4. Secondly, factors that affect TH binding are more apt to alter T4 assays than T3, as T4 is normally more tightly bound to TBG than is T3.

Serum Thyroid-Stimulating Hormone

Serum TSH in NTIS is typically normal or reduced and may be markedly low, although usually not less than 0.05 μU/mL.[1,10,11,19,25,33] It should be noted, however, that NTIS may have a major impact on pulsatile TSH secretion, which may fall to a large extent in patients with critical illness, as reported by Van den Berghe et al.[34] Therefore, in view of negative feedback regulation in the HPT axis, TSH levels are inappropriately low for the observed serum T4 and T3. Serum TSH in patients with NTIS may have reduced biological activity, perhaps because of reduced thyrotropin-releasing hormone (TRH) secretion with reduced TSH glycosylation as a result. Of interest, elevation of TSH above normal commonly occurs transiently if patients recover from NTIS.[35] This may indicate that these patients are recovering from a hypothyroid state, during which the ability of the pituitary gland to respond had been temporarily inhibited.

Patients treated in ICUs for a prolonged period of time show dramatically diminished TSH pulsatility, characterized by an absent nocturnal TSH surge and a decreased TSH pulse amplitude. Pulsatile TSH secretion was positively related to a low serum T3 level, in keeping with the notion that the reduced production of THs in prolonged critical illness may have, at least in part, a neuroendocrine origin.[36] Indeed, a postmortem investigation of TRH mRNA expression in the hypothalamic paraventricular nucleus (PVN) of patients with NTIS biochemically documented from serum samples taken less than 24 hours before death showed decreased TRH expression in patients with prolonged critical illness (Fig. 83.1). In fact, the decrease in total TRH mRNA expression in the PVN significantly correlated with the decrease in both serum TSH and T3, but not in T4. These patients had not been treated with glucocorticoids or dopamine.[37]

Further support for a major role for the hypothalamus in the resetting of the HPT axis in NTIS came from the observation that a continuous administration of TRH to patients with prolonged critical illness partially restored the serum concentrations of T3, T4, and TSH, especially when combined with growth hormone secretagogues.[38]

KEY POINTS

- During NTIS, TSH levels are inappropriately low for serum hormone levels reflecting altered HPT axis feedback regulation, partly resulting from reduced hypothalamic secretion of TRH.

THYROID HORMONE TRANSPORT

TH needs to be taken up in the cell by specific TH transporters like monocarboxylate transporter 8 (MCT8), monocarboxylate transporter 10 (MCT10), and organic anion transporting polypeptide family 1C1 (OATP1C1) to exert its action at the cellular level.[39] In the liver, NTIS affects TH transport at the level of the plasma membrane. Many years ago it was shown that decreased liver adenosine triphosphate and increased concentrations of compounds that inhibit T4 transport into the liver (bilirubin, nonesterified fatty acids) may contribute to reduced transport of T4 into the hepatocyte.[40] Using deiodination of T4 as an index of cellular transport of T4 into rat hepatocytes, Lim and coworkers[41] and Vos and colleagues[42] found that serum from patients with NTIS inhibited T4 uptake, elevated nonesterified fatty acids and bilirubin, and reduced albumin were considered to play a role. Inhibition of uptake of T4 into hepatocytes caused by sera of patients with NTIS also was observed by Sarne and Refetoff.[43] Recently, studies have been published about the effect of illness or inflammation on TH transporter expression in specific tissues, and it is clear that tissue TH transporter expression itself is also affected during NTIS. Interestingly, changes in liver TH transporter expression appear to differ between various animal models of NTIS; acute illness lowers Slc16A2 (MCT8) and Slc16A10 (MCT10) expression, whereas chronic inflammation results in decreased Slc16A2 mRNA expression and an increase in Slc16A10 mRNA. By contrast, lethal bacterial sepsis affects hepatic TH transport only marginally.[44] Tissue-specific changes will be discussed in more detail later.

In theory, reduced cellular TH uptake by itself would cause tissue hypothyroidism, which is generally not observed. Therefore, it is likely that reduced cellular uptake, if present, is just one of many factors involved in NTIS.

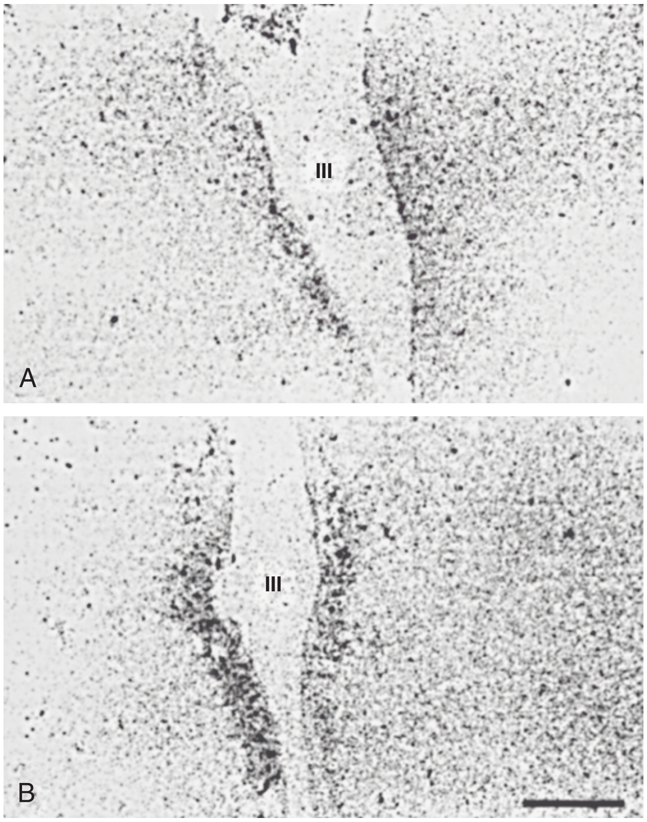

Fig. 83.1 *In situ* hybridization study demonstrating mRNA for TRH in the periventricular nuclei of (A) a subject who died after prolonged illness and NTIS and (B) a subject who experienced acute death. In patients with NTIS, mRNA for TRH is significantly reduced. *mRNA*, Messenger ribonucleic acid; *NTIS*, nonthyroidal illness syndrome; *TRH*, thyrotropin-releasing hormone. (From Lu B, Moser AH, Shigenaga JK, et al. Type II nuclear hormone receptors, coactivator, and target gene repression in adipose tissue in the acute-phase response. *J Lipid Res.* 2006;47:2179–2190.)

THYROID HORMONE METABOLISM AND ACTION

Intracellular TH is metabolized via iodothyronine deiodinases, a group of selenium cysteine-containing enzymes that are able to remove an iodine atom from the inner or outer ring of TH. Three types are known: type 1 (D1) catalyzes inner- and outer-ring monodeiodination, type 2 (D2) catalyzes only outer-ring deiodination (converting its preferred substrate T4 into T3), and type 3 (D3) catalyzes only inner-ring monodeiodination (degrading its preferred substrate T3 into T2, but also T4 into rT3, thereby inactivating TH).[45] Changes in type D1, D2, and D3 expression and activity in a variety or organs and tissues have been described in NTIS.[46]

T3 binds to TH receptors (TR) mediating genomic (canonical) and noncanonical actions.[47,48] Three T3-binding TRs have been described: TRα1, TRβ1, and TRβ2. TRα1 and TRβ1 are important in regulating TH target genes in peripheral tissues and are differentially expressed between organs. TR expression levels are also affected during illness.[46]

KEY POINTS

- Tissue TH concentrations during NTIS do not necessarily reflect serum concentrations and may decrease, remain unaltered, or even increase according to the organ and type of illness studied.

TISSUE- AND ORGAN-SPECIFIC RESPONSES IN NONTHYROIDAL ILLNESS SYNDROME

In contrast to a uniform whole-body response, there are wide variations in responses to TH supply and action in different organs and tissues, and between the response to acute illness and chronic illness. These multifactorial systems involve serum TH levels, TH transporters, deiodinase, and TR responses that are under different regulation in individual tissues.[46,49]

Hypothalamus

Not much is known about the effects of NTIS on hypothalamic TH transporters. Inducing critical illness in experimental animals induced increased MCT10 and OATP1C1 expression, while hypothalamic MCT8 mRNA expression remained unaltered. Because these changes were unrelated to local tissue T3 concentrations, their functional consequences remain unclear at present.[50]

Both D2 and D3 are expressed in the human hypothalamus. D2 is mainly expressed in glial cells of the infundibular nucleus and median eminence and in cells lining the third ventricle, while D3 is present in neurons of the PVN, supraoptic nucleus, and infundibular nucleus.[51] Because these studies were performed in postmortem tissue specimens, no data are available on TH metabolism in the human hypothalamus. Studies in rodents, however, have shown that hypothalamic D2 is a determinant of hypothalamic T3 production.[52] Furthermore, the administration of bacterial endotoxin (or lipopolysaccharide [LPS]), which is an established experimental model of acute NTIS, was reported to increase both D2 mRNA expression[53] and enzyme activity in the hypothalamus, specifically in tanycytes lining the third ventricle[54] (Fig. 83.2). Increased D2 activity is not specific for the acute phase of illness, as hypothalamic D2 activity is upregulated both in mice with bacterial sepsis[55] and in rabbits with critical illness.[50] Hypothalamic D3 is regulated in a reciprocal fashion: acute and chronic inflammation decrease D3 expression.[56,57] The observed D2 increase and D3 decrease probably result in net increased local T3 production, which may contribute to the decreased TRH mRNA expression in the PVN, as observed during illness both in animals and in humans.[57-59] An elegant study using an *in vitro* coculture system confirmed that LPS modulates glial D2 as well as neuronal D3 expression, resulting in altered T3 concentrations.[60] This has been confirmed by a recent study showing that the LPS-induced decrease of D3 in a neuronal cell line resulted in increased cellular T3 concentrations in the same cells.[61]

Hypothalamic TR mRNA expression by itself does not show dramatic changes during NTIS,[50] but changes in specific TR isoform expression in PVN neurons have not been carefully evaluated during NTIS. This could be of interest because the LPS-induced increase in hypothalamic D2 and decrease in hypothalamic D3 is exaggerated in $TR\beta^{-/-}$ mice compared with wild-type (WT) mice,[56] indicating that TRβ modulates the hypothalamic deiodinase responses to acute inflammation. In line with this, $TR\alpha^{0/0}$ mice do not display prominent changes in hypothalamic D2 and D3 responses to LPS.[62]

Very few studies have addressed hypothalamic T3 concentrations during NTIS directly. Mebis et al. showed that prolonged illness in rabbits does not increase hypothalamic T3 tissue concentrations, despite increased D2 expression, but these results should be interpreted carefully given the technical difficulties in selectively harvesting infundibular nucleus and PVN samples for the assessment of T3 concentrations.[50] Of note, in postmortem human hypothalamic specimens, T3 concentrations were even lower in NTIS patients compared with patients with acute death from trauma[63] (Table 83.2).

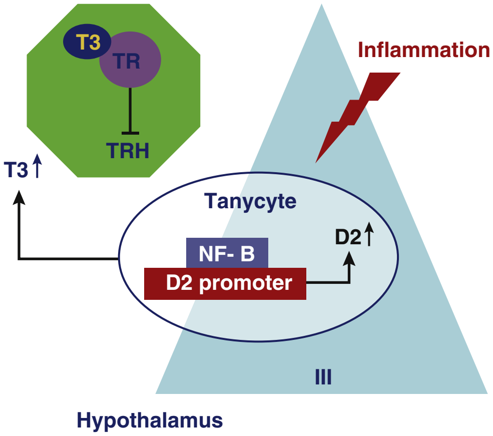

Fig. 83.2 Schematic model of hypothalamic thyroid hormone signaling during inflammation. Inflammation activates the nuclear factor (*NF*)-κB pathway in tanycytes, specialized cells lining the third ventricle (*III*). Tanycytes express type 2 deiodinase (*D2*), the main triiodothyronine (*T3*)-producing enzyme in the brain, the promoter of which contains NF-κB–responsive elements. Binding of NF-κB increases D2 expression and activity, and this stimulates the conversion of the prohormone thyroxine into T3. T3 will enter adjacent neurons and bind to neuronal thyroid hormone receptors, thereby regulating transcriptional activity of thyrotropin-releasing hormone (*TRH*). (Used with permission from Fliers E, Bianco AC, Langouche L, et al. Thyroid function in critically ill patients. *Lancet Diabetes Endocrinol.* 2015;3:816–825.)

Pituitary

Data on the pituitary gland are few. D2 levels have not shown consistent changes in animal models, whereas TRβ2 expression is reduced in acute NTIS.[64] In humans with fatal illness, pituitary T3 levels were low.[63] The overall picture is of central downregulation of the hypothalamus and pituitary gland and low levels of tissue T3 despite increments in transporter activity and D2 deiodinase. These findings fit with the observed correction of TSH and TH levels in human NTIS through administration of TRH.

Liver

Hepatic TH metabolism has been extensively studied during NTIS in both humans and experimental animals. The main TH transporters in liver are MCT8 and MCT10, and the expression of these transporters is affected during NTIS. In humans, MCT8 and MCT10 expression has been studied in postmortem liver biopsy samples from critically ill patients and compared with liver biopsy samples from patients after elective abdominal surgery (acute illness). Liver MCT8 expression was markedly increased in patients with prolonged illness compared with acute illness, while MCT10 expression did not differ. However, healthy controls were not available, which makes the study difficult to interpret.[65]

TH transporter expression was also studied in different NTIS animal models and shows differential changes; acute illness in mice lowers MCT8 and MCT10 expression, whereas chronic inflammation results in decreased MCT8 expression and an increase in MCT10. Lethal bacterial sepsis in mice affects hepatic TH transport only marginally. It remains questionable, however, whether the (sometimes small) alterations in liver TH transporter expression were instrumental in affecting liver TH concentrations.[44]

Both D1 and D3 are expressed in liver, although D3 is expressed only at very low levels in a healthy liver. During NTIS, D1 and D3 are heavily affected. Liver D1 is reduced during acute and prolonged

TABLE 83.2 Tissue T3 Concentrations in Nonthyroidal Illness Syndrome (nmol of T3/kg of Wet Weight)

	CONTROL GROUP			NTI GROUP	
Tissue	**Mean**	**SD**	**P**	**Mean**	**SD**
Cerebral cortex	2.2	0.9	<0.05	1.2	1.1

Most of the NTI patients received dopamine at some time in their ICU stay.

NS, Not significantly different; *NTI*, nonthyroidal illness; *T3*, triiodothyronine; *SD*, standard deviation.

(From Arem R, Wiener GJ, Kaplan SG, et al. Reduced tissue thyroid hormone levels in fatal illness. *Metabolism.* 1993;42:1102–1108.)

illness in both human and experimental animals.[53,66,67] Liver D3 is differentially regulated; D3 activity decreases during acute inflammation in mice[53] but was induced in the liver of severely ill patients.[18] Furthermore, liver D3 activity was positively correlated with serum rT3 concentrations and negatively correlated with serum T3 levels.[68] A rabbit model for prolonged critical illness showed identical clinical, biochemical, and endocrine features as seen in ICU patients,[69,70] and liver D3 activity tends to increase in these animals.[67] The response of D3 to illness may depend on energy status; fasting results in increased liver D3 activity in rodents,[71,72] and prolonged illness is associated with diminished food intake.[73] The meaning of the observed changes in liver deiodinase activity is currently unknown, as experiments performed with D3 knockout (D3KO) mice showed that D1 nor D3 contributed to the observed changes in serum TH concentrations during sepsis: the changes in TH levels were similar in D3KO and WT mice. In addition, basal liver D1 activity was relatively low in D3KO mice and not responsive to sepsis, suggesting that changes in liver D1 were also not critical for the decrease in serum TH concentrations.[55]

Both TRα and TRβ are expressed in liver, and mRNA expression of the TR is differentially affected during illness, depending on the severity and duration. TRα and TRβ decreased during acute illness in rodents[53,74] but did not change during chronic inflammation and bacterial sepsis in mice. Human data are not consistent: TRα and TRβ mRNA expression in liver biopsies from patients with chronic liver disease before liver transplantation both increased in association with low serum T3 and T4 levels.[75] In postmortem liver biopsies from ICU patients, the TRα1/TRα2 ratio increased with the severity of illness.[76] Chamba et al. studied hepatic TRα1, TRα2, and TRβ1 and T3 target gene expression in patients with a variety of chronic liver diseases and found no changes in TR or T3 target gene expression, despite reduced serum TH levels, indicating a euthyroid condition in the liver of these patients.[77] These findings are in line with the chronic inflammation mouse and rat models published to date and represent another example of a dissociation between serum TH levels and TH action at the organ level during NTIS. However, there is a caveat, as proper TR antibodies are lacking, which makes it impossible to study the effect of illness on TR protein expression.

In general, illness results in marked changes in TH transporter expression, deiodinase activity, and TR expression. These changes are associated with reduced metabolic activity in the liver, reduced T3 target gene expression, and lowered hepatic TH concentrations.[44,63,78,79]

Muscle

Muscle is an important T3 target tissue, as a variety of genes expressed in muscle are either positively or negatively regulated by T3. Local muscle thyroid accessibility and availability are regulated by the TH transporters MCT8 and MCT10 and D2 and D3, respectively. TRα1 is the major TR isoform in muscle, but TRβ1 is also expressed.[65,80,81] Local conversion of T4 by D2 is important in muscle function, as 40% of nuclear-bound muscle T3 in rat is derived from local production,[40] and even more in humans.[82,83]

Several studies have reported altered muscle TH metabolism during NTIS, both in acute and more chronic models.[46] In mice, muscle TH transporter expression is low during acute inflammation and bacterial sepsis and did not change during chronic inflammation. The same changes are also observed in patients; MCT8 expression is remarkably low in muscle tissue of patients during acute surgical stress compared with patients with prolonged illness.[65] Muscle MCT8 and MCT10 mRNA expression was also studied in a rabbit model of prolonged illness, and the findings differed from the human samples, as MCT8 mRNA expression did not change, while MCT10 markedly increased. THs are thought to play a role in the regulation of TH transporter status during NTIS because TH treatment in a rabbit model of NTIS returns the transporters to normal.[65]

During acute inflammation in mice, muscle D2 mRNA expression increases, while muscle D3 decreases,[84] and the changes in deiodinase expression coincide with decreased TR expression.[44] D2 mRNA expression and activity were also studied in skeletal muscle tissue of patients with acute surgical stress compared with healthy controls. Serum T3 levels decreased significantly during the surgical procedure, but D2 mRNA expression and activity in muscle did not change compared with controls.[85]

A few studies have been published describing the effect acute illness on T3 signaling in muscle tissue. The expression of *UCP3* (both mRNA and protein), a T3 target gene, increased in the skeletal muscle of mice during acute sepsis[86] and inflammation.[80] In agreement, UCP3 expression increased in the skeletal muscle of NTIS patients, coinciding with increased D2 mRNA expression, although a variety of other T3 target genes (*SERCA*, *MHC,* and *GLUT4*) did not change.[87] The clinical relevance of increased muscle T3 signaling is unclear at present. In contrast, chronic inflammation in an experimental mouse model results in simultaneously increased D2 and D3 activity.[88] This may result in a coordinated breakdown of both T4 and T3, ultimately leading to increased intracellular T2 levels. Both T3 and T2 are known to regulate mitochondrial activity in skeletal muscle.[89,90]

Bacterial sepsis lowers muscle D2 mRNA expression in mice[88] and in patients with septic shock, while D2 activity was hardly detectable in human skeletal muscle and did not differ from the controls undergoing surgery.[81] In contrast, muscle D3 activity increased in septic patients compared with controls, possibly enhancing T3 clearance in muscle. Furthermore, TRβ1 mRNA, as well as RXRγ mRNA, decreased during sepsis. During *Streptococcus pneumoniae* infection in mice, D3 mRNA expression did not change, while D3 activity tended to increase.[88] The combination of decreased D2 expression and unaltered or increased D3, observed in both human and experimental sepsis models, may result in decreased T3 bioavailability in muscle tissue. However, muscle mRNA expression of *UCP3*, a T3 target gene, is unaltered in the muscle tissue of septic patients compared with control patients,[81] and myogenin, another T3-responsive gene, did not change in murine muscle during chronic inflammation and bacterial sepsis.[44] These observations suggest that the downregulation of TR expression may be an adaptation to restore TR occupancy and T3 signaling. To make it even more complicated, muscle T3 and T4 concentrations were lower in all animal NTIS models compared with controls, despite variable alterations in transporter expression and deiodinating enzymes.[44]

TR expression has also been studied in the diaphragm, which is the main respiratory muscle, with high energy demands. Acute inflammation in mice profoundly decreases TRα1 and TRβ1 mRNA expression in the diaphragm, in association with decreased expression of coactivators involved in nuclear receptor activation.[91] The effects of bacterial sepsis and chronic inflammation on the diaphragm have also been studied; sepsis resulted in increased D3 and decreased D2 expression, which was associated with reduced TH signaling. Chronic inflammation, on the other hand resulted, in decreased D3 expression.[92] Thus, the situation in the diaphragm with respect to D2 and D3 expression is identical to that observed in skeletal muscle during bacterial sepsis and chronic inflammation.[44]

The differential regulation of muscle deiodinase expression among acute inflammation, chronic inflammation, and sepsis may relate to the severity of illness and support the concept that the net result of altered muscle deiodinase expression determines muscle function during specific stages of illness.

Adipose Tissue

White adipose tissue (WAT) is a key T3-responsive metabolic organ. WAT expresses multiple genes involved in TH transport and metabolism, such as *MCT8, D2, D3, TRα1, TRβ1,* and a variety of co-activators involved in TR signaling.[93] Illness affects adipose tissue via stimulating lipolysis, which is a partly T3-regulated process.[94] The effect of illness on adipose tissue, however, has not been extensively studied. Acute inflammation induced in experimental animals resulted in decreased mRNA expression of TRα1 and TRβ1, which is associated with a decrease in coactivators and reduced expression of the well-known T3 target genes *ME* and *Spot14*.[93] LPS administration also resulted in increased D2 mRNA expression and a decrease in D3 mRNA expression; the increase in D2 mRNA expression was, however, not accompanied by an increase in D2 enzyme activity.[95]

In contrast, subcutaneous WAT of NTIS patients with septic shock within 5 days after admission to the ICU showed moderately decreased MCT8 and TRβ1/TRα1 mRNA expression, while D2 mRNA expression and D3 activity did not change.[81] Surprisingly, UCP3 expression was increased, suggesting increased T3 signaling. This again shows the dissociation between T3 uptake and TR expression on the one hand and T3 action on the other. As increased T3 signaling in adipose tissue during sepsis is opposite to decreased T3 signaling observed during nonlethal acute inflammation, this again shows the differential response in different metabolic organs during different states of NTIS.

KEY POINTS

- A novel role for TH metabolism in innate immune cells, including neutrophils and monocytes/macrophages, was shown. Its role in susceptibility to infections is unclear at present.

Neutrophils and Macrophages

Innate immune cells are part of the innate immune system, which is responsible for the host defense against invading pathogens via a variety of bacterial killing mechanisms, including phagocytosis or the production of specific inflammatory signals. Important players of the innate immune system are neutrophils and macrophages, and recent studies indicate that the cellular function of these cells is highly dependent on the availability of intracellular TH, regulated via D3 and D2, respectively. As observed in other tissues, D3 and D2 expression alters during inflammation, supporting the role of TH in cellular function.[96]

D3 protein is highly expressed in infiltrating murine neutrophils during both bacterial infection and sterile inflammation[97,98] and is also expressed in human neutrophils.[99] D3 activity was strongly elevated in a subcutaneous abscess containing predominantly activating neutrophils.[97] D3 in human neutrophils was found in intracellular granules involved in bacterial killing and in early stage neutrophil extracellular traps.[99] Mice that lack D3 have impaired bacterial killing upon infection with *S. pneumoniae*.[55] In line with this observation, D3 knockdown in zebrafish embryos with pneumococcal meningitis resulted in increased mortality and reduced neutrophil infiltration during infection. *In vitro* experiments with stimulated neutrophils from female D3KO mice showed that NADPH-oxidase activity is impaired compared with WT neutrophils.[100] These findings strongly support a critical role for the TH inactivating enzyme D3 in neutrophil function during infection.

Macrophages contain several essential elements of intracellular TH metabolism; D2 is the main deiodinase present, and TRα1 the dominant TR.[101] Activation of macrophages by bacterial endotoxin results in the induction of D2, together with TRα1 and MCT10, indicating a shift towards increased TH action during inflammation.[101] Furthermore, D2 knockdown resulted in impaired macrophage phagocytosis and blunted cytokine response to LPS stimulation.[101,102] In zebrafish embryos, D2 knockdown increased mortality during pneumococcal meningitis, and this can be restored by T3 administration during infection.[102] Increased intracellular T3 availability and action thus appear to play a crucial role in macrophage function.

KEY POINTS

- The role of inflammatory pathways in non-systemic changes during NTIS has begun to be clarified.

MECHANISM OF ALTERED THYROID HORMONE METABOLISM IN NONTHYROIDAL ILLNESS SYNDROME

It has gradually become clear that the cause of NTIS is multifactorial and may differ in different groups of patients. Specifically, the changes in liver disease and renal disease are somewhat different from those occurring in other forms of illness. Several mechanisms are known to be involved in the illness-induced alterations in the HPT axis and TH target tissues, and these mechanisms will be discussed later. Inflammatory mediators play an important role and have been studied extensively using a variety of *in vivo* and *in vitro* models. Well-studied NTIS animal models are acute illness, induced by administration of a sublethal dose of LPS[53,54]; chronic inflammation, induced by injection of turpentine in the hind limb, ultimately resulting in the formation of an abscess[97,103]; bacterial sepsis, induced by inoculation with *S. pneumoniae* or intraperitoneal injection with *Escherichia coli*[98,104]; and prolonged critical illness in rabbits induced by burn injury.[105] Characteristic for these models is the downregulation of serum TH concentrations despite the variability of the inflammatory response. The recent availability of a variety of transgenic mice models makes it possible to study the specific contribution of genes involved in the pathogenesis of NTIS. The role of inflammatory mediators involved in altered TH metabolism has been studied extensively *in vitro* using a variety of cell lines that were stimulated with LPS or proinflammatory cytokines with and without specific inhibitors.

Downregulation of Hypothalamic and/or Pituitary Function

Considerable evidence suggests that an alteration in hypothalamic and pituitary function causes the low production of T4, which in turn causes the low production of T3. In rats, starvation reduces hypothalamic mRNA for TRH, reduces portal serum TRH, and lowers pituitary TSH content.[106] One study documents low TRH mRNA in hypothalamic paraventricular nuclei in NTIS patients.[37] In addition, several animal studies show that hypothalamic TRH expression also decreases after acute inflammation,[107] chronic inflammation,[57] and prolonged critical illness in rabbits.[50] Responses to administered TRH vary in different reports, being suppressed or even augmented.[33,108] Administration of TRH has been suggested as an effective means of restoring serum hormone levels to normal in individuals with NTIS. A recent report of great significance by Van den Berghe and coworkers proves that administration of TRH to patients with severe NTIS leads directly to increased TSH levels, increased T4 levels, and increased T3 levels.[38] These data provide strong support (albeit not proof) for the role of diminished hypothalamic function as an important factor causing NTIS.

The illness-induced suppression of TRH in the PVN is thought to be mediated by increased local T3 production via increased D2 expression in tanycytes and decreased D3 expression in neurons.[61] Inflammatory mediators contribute to the illness induced alteration in both D2 and D3; the mechanisms will be discussed later.

An additional factor in the pathogenesis of the illness-induced downregulation of hypothalamic hypophysiotropic TRH neurons may be regulation by afferent pathways projecting from brainstem nuclei to the PVN. LPS is known to modulate autonomic centers in the lower brainstem, in turn activating hypophysiotropic corticotrophin-releasing hormone (CRH) neurons in the PVN.[109,110] Like CRH neurons, hypophysiotropic TRH neurons receive neural input from the brainstem. However, as transsection of these ascending pathways did not affect the LPS-induced decrease of TRH expression in the PVN, neural input from the brainstem appears to be relatively unimportant in this respect.[111]

Corticosterone is also known to affect TRH expression directly and could also contribute to the TRH decrease during illness.[112] The diurnal variation in glucocorticoid levels at least in part controls the normal diurnal variation in TSH levels, perhaps by affecting pituitary responsiveness to TRH.[113] High levels of glucocorticoids in Cushing disease suppress TSH and cause a modest reduction in serum hormone levels.[114] High levels of glucocorticoids are known to suppress the pituitary response to TRH in humans.[115] Stress-induced elevation of glucocorticoids in animals causes suppression of TSH and serum T4 and T3 hormone levels.[116] Thus, stress-induced glucocorticoid elevation may be one factor affecting TRH and TSH production.

TRH is also decreased during starvation, suggesting that part of the observed TRH decrease during illness may be a result of the diminished food intake associated with illness. However, in a mouse model for chronic inflammation, diminished food intake does not play a role in the observed TRH decrease.[57]

Pituitary production of TSH is often diminished despite low serum TH levels, as described in patients[34] and in a wide variety of animal models.[50,53,54,57] The mechanisms involved are incompletely understood, although it has been shown that the illness-induced decrease of TSHβ expression depends on functional TR signaling because TRβ$^{0/0}$ mice show a blunted TSHβ decrease upon LPS stimulation compared with WT mice.[56] It is also hypothesized that intrapituitary conversion of T4 to T3 was increased, which allowed the pituitary gland to remain euthyroid while the rest of the body was actually hypothyroid. While some data supported this idea in a uremic rat model of NTIS,[117] careful studies in both experimental animals and humans yielded conflicting results.

The most obvious possibility is that low TSH stems from diminished TRH production, as previously described. It must also be remembered that the defect in pituitary function is not restricted to TSH, but that LH and FSH are also suppressed in seriously ill patients, and testosterone is reduced, in contrast to the generally augmented glucocorticoid response. Quite possibly, these changes are the effect on the hypothalamus of neural integration of multiple factors, including stress, starvation, glucocorticoids, and cytokines.

Cyrokines

Cytokines have been implicated in the development of NTIS for more than two decades. Interleukin (IL)-6 was found to be negatively correlated with serum T3 concentrations in hospitalized patients.[118] In a series of septic patients studied shortly after admission to an ICU, total T4, free T4, total T3, and TSH were depressed, and IL-1β, soluble interleukin-2 receptor (sIL-2R), IL-6, and tumor necrosis factor (TNF)α were elevated.[119] In mice, acute inflammation is associated with an acute increase of serum IL-6 and TNFα concentrations.[64] A causal role for IL-6 in the development of NTIS in mice was shown, as IL-6 knockout mice show a less pronounced drop in serum T3 during illness.[120] However, acute injection of cytokines failed to induce NTIS-like features in mice, except for injection of interferon gamma (IFNγ), which reduces serum T3 and T4.[64] In humans, subcutaneous administration of IFNγ did not alter TNFα levels but caused a small elevation of IL-6 levels, and thus did not support a role for IFNγ in the pathogenesis of the euthyroid sick syndrome in humans.[121]

Chronic infusions with IL-1 and IL-6 mimic certain symptoms, such as decreased serum T4 and T3 and decreased TRH expression in the hypothalamus in mice,[122] whereas chronic IL-1β infusions mimics certain aspects of NTIS in rats.[123] Van der Poll and colleagues[124] studied the effect of IL-1 receptor blockade in human volunteers to determine if it could alter the NTIS induced by endotoxin. Blockade of IL-1 signaling was achieved by infusing recombinant human IL-1 receptor antagonist, but this did not prevent the drop in T4, free T4, T3, and TSH or the rise in rT3 caused by endotoxin. Stouthard and coworkers[125] gave recombinant human IL-6 chronically to human volunteers. Short-term infusion of IL-6 caused a suppression of TSH, but daily injections over 42 days caused only a modest decrease in T3 and a transient increase in rT3 and free T4 concentrations.

Infusion of recombinant TNFα in man by van der Poll and coworkers[126] produced a decrease in serum T3 and TSH and an increase in rT3. However, blocking TNFα by a recombinant TNF receptor–IgG fusion protein did not prevent the endotoxin-induced NTIS in humans,[127] indicating that TNFα alone did not cause the changes in hormone economy induced by endotoxin.

A variety of studies (reviewed by de Vries and coworkers) clearly show that cytokines, either alone or synergistically, are able to downregulate various components of the TH synthesis pathway in the thyroid via an effect on iodide uptake and thyroglobulin synthesis, ultimately leading to decreased secretion of T4 and T3.[128] Proinflammatory cytokines are also able to affect TH metabolism and action in hepatocytes; IL-1β decreases TRβ, TRα1, and D1 mRNA expression in a human hepatoma cell line (HepG2),[129,130] and TNFα, IL-1, and IL-6 decrease the capacity of T3 binding to the TR.[131]

In summary, the potential interaction between proinflammatory cytokines and the HPT axis is certainly complicated, as cytokines, increased in many infectious, inflammatory, and neoplastic conditions, themselves operate in a network via the stimulation of other proinflammatory and antiinflammatory cytokines. Many studies therefore fail to pinpoint one cytokine as the crucial mediator, but we can be convinced that striking changes in cytokines cooccur during NTIS and probably play a pathogenic role.

Nuclear Factor κB

Recent studies indicate a role for nuclear factor κB (NF-κB) in the pathogenesis of NTIS. The NF-κB protein family is an inflammatory signal transduction pathway consisting of several subunits, of which RelA (the 65-kD subunit of NF-κB) acts as a transcriptional activator able to bind to the Dio2 promoter.[132,133] LPS stimulation of primary tanycyte cell cultures increases D2 and RelA mRNA expression and RelA phosphorylation, confirming activation of this pathway. Inhibition of RelA with chemical inhibitors prevented the LPS-induced D2 increase, indicating that NF-κB signaling is essential for the upregulation of D2 in tanycytes *in vitro*.[134] Conditional elimination of RelA in tanycytes using transgenic mice shows that NF-κB is essential for the LPS-induced hypothalamic D2 increase and TRH decrease *in vivo*. The central changes in the HPT axis are, however, not required for the downregulation of Tshβ expression and serum TH concentrations.[135]

Certainly, one important cause of the drop in serum T3 is a decreased generation of T3 by type 1 iodothyronine deiodinase.[136] NF-κB is also thought to play a role in the illness-induced decrease of D1. TNFα impairs the T3-dependent induction of D1 expression in HepG2 cells via interference of NF-κB with TR function.[137] Kwakkel et al. showed that the IL-1β–induced decrease in TRβ mRNA expression in HepG2 cells depends on NF-kB signaling, and the decreases in D1 on both NF-kB and AP-1 signaling.[129,130]

Alternative Mechanisms

The *DIO1* gene is positively regulated via a TR/retinoid-X receptor (RXR) heterodimer, indicating that decreased *DIO1* expression may result from reduced TR and/or reduced RXR expression.[138] Liver TRβ1 expression decreases during acute inflammation in mice,[53,74,139] and Yu et al. proposed a very elegant mechanism for the TRβ-mediated repression of liver D1 during acute inflammation. They showed both *in vivo* and *in vitro* that adding exogenous coactivator SRC-1 attenuates the illness-induced liver D1 decrease.[140,141] This indicates that competition for limiting amounts of SRC-1, which is a shared coactivator for TR and inflammatory signaling pathways, could be responsible for the illness-induced D1 decrease. Indeed, restoration of liver Dio1 expression by exogenous SRC-1 prevents the fall in serum TH levels after LPS[141] (Fig. 83.3).

An alternative possibility is the availability of a specific cofactor glutathione (GSH), which is required for D1 catalytic activity. Decreased amounts of GSH may play a role in the illness-induced decrease of liver D1 activity, as indicated by a study performed by Wajner et al. showing that addition of N-acetyl-cysteine, an antioxidant that restores intracellular GSH levels, prevents the IL-6–induced suppression of D1.[142]

Although these studies provide mechanisms behind the illness-induced D1 decrease in the liver, at this stage, the importance of decreased liver D1 for the development of NTIS is unclear, as studies in D1/D2 knockout mice showed similar responses to LPS administration with regard to serum T4 and T3 compared with WT littermates.[143] Although the effect of a lack of D1 on illness-induced liver T3 concentrations has not been documented, the suppression of liver D1 activity was correlated with decreased hepatic T3 concentrations in rabbits with critical illness.[79]

Changes in D3 are observed in liver and muscle, depending on the type and the timing of the illness.[18,84,88] These changes may be independent of inflammatory pathways, as neither sepsis nor chronic inflammation induces phosphorylation of the NF-κB and ERK pathways.[88] In cardiomyocytes, D3 is upregulated during myocardial infarction.[144,145] Hypoxia because of decreased tissue perfusion is thought to play a role in the observed increase, as both D3 and hypoxia inducible factor (HIF)1α are upregulated in the hypertrophic heart. HIF1α activity is regulated by prolyl hydroxylases that prime HIF1α for degradation.[146] Under hypoxic conditions, HIF1α stabilizes and translocates to the nucleus, dimerizes with HIF1β, and activates D3 gene transcription.[147] In addition, during inflammation NF-κB also directly enhances *HIF1α* gene transcription, thereby increasing total HIF1α availability.[148] Increased D3 expression during myocardial infarction is also associated with increased expression of a specific set of microRNAs that may enhance the proliferative capacity of cardiomyocytes.[149]

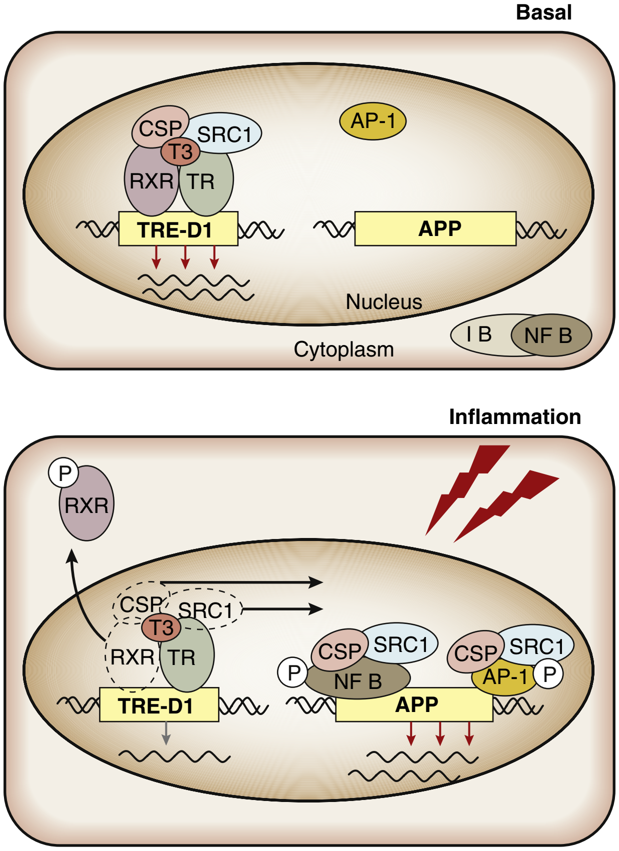

Fig. 83.3 Schematic model of the proposed mechanisms involved in illness induced downregulation of liver type 1 deiodinase (*D1*) expression. In this model, limited amounts of SRC-1, a coactivator for both nuclear factor (*NF*)-κB and thyroid hormone receptor (*TR*)β1, decrease liver D1 mRNA expression as a result of competition between cytokine-induced NF-κB and the TRβ1/D1 complex for SRC-1. Note the role of decreased nuclear retinoid-X receptor α protein by lipopolysaccharide-induced rapid nuclear export via JNK phosphorylation and subsequent proteasomal degradation. KEY POINTS

- Research on NTIS in patient populations should take (parenteral) feeding into account as a major determinant of NTIS as well as clinical outcome.

Energy Status

Critical illness is associated with marked loss of appetite and poor nutritional intake.[150] As food deprivation in healthy subjects induces a NTIS response similar to critically ill patients, decreased caloric intake during illness may be a major determinant of the development of NTIS, in addition to many other factors already discussed (Fig. 83.4). Three clinical studies involving different nutritional strategies indeed indicated that

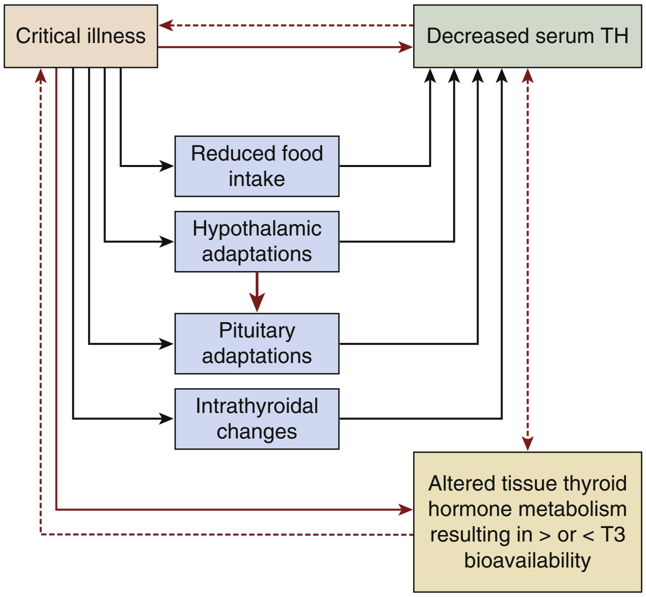

Fig. 83.4 Schematic representation of the variety of changes occurring during critical illness. Solid lines represent a causal relation, while a dashed line represents a probable effect. The scheme is based on both experimental and human studies. The net result of altered tissue thyroid hormone (*TH*) metabolism may be beneficial or maladaptive, dependent on disease duration and severity. *T3*, triiodothyronine. (Used with permission from Fliers E, Bianco AC, Langouche L, et al. Thyroid function in critically ill patients. *Lancet Diabetes Endocrinol.* 2015;3:816–825.)

decreased caloric intake during critical illness is associated with a more pronounced NTIS.[151-153] The mechanism by which fasting induces a decrease in serum TH is multifactorial and includes a decrease in serum leptin, contributing to downregulation of hypothalamic hypophysiotropic TRH neurons, allowing persistence of low serum TSH.[154]

Leptin plays a key role in the control of TH levels during starvation in animals. During starvation, circulating leptin levels drop. This induces diminished stimulation of TRH, and thus diminished secretion of TSH and lowered TH levels. Administration of leptin appears to work via the arcuate nucleus of the hypothalamus to induce production of proopiomelanocortin, and thus α melanocyte-stimulating hormone (αMSH) and reduce Agouti-related protein (AgRP). Normally, αMSH stimulates the melanocortin 4 receptor (MC4R), whereas AgRP suppresses it. Presumably through these actions, a lack of leptin during starvation leads to diminished stimulation of the MC4R receptor on the TRH neurons in ventricular nuclear centers, and thus diminished TRH secretion. Administration of leptin partially reverses this sequence.[155] These actions appear to be part of an energy-conserving scheme related to thyroid changes during starvation and are associated with leptin-induced increase in appetite, decreased energy expenditure, and modified neuroendocrine function. The relevance of this to human physiology is as yet unclear, but the data strongly suggest that leptin is involved in the downregulation of thyroid function during acute starvation.[156,157] In clinical trials, stimulation of growth hormone secretion by growth hormone secretagogues led to increased insulin and leptin levels in severely ill ICU patients. To date, studies of leptin levels in patients with NTIS have indicated they are normal or elevated, not low.[38] Liver D3 increases during fasting in mice, and this increase is dependent on the drop of leptin.[71] Increased activity of D3, however, is not supposed to contribute to the clearance of T3 and T4 from plasma during fasting because D3KO and WT mice show the same decreased serum TH concentrations in response to fasting.[158]

CLINICAL IMPLICATIONS AND THERAPEUTIC CONSIDERATIONS

It is straightforward that the typical clinical parameters of severe hypothyroidism are absent in patients with NTIS. The clinical endocrinologist is frequently presented with a severely ill patient in the ICU without a history of pituitary or thyroid disease with a low (free)T4, a low or normal TSH, and, if measured, a very low (free)T3. If T4 is below 4 µg/dL in this setting, the diagnosis of NTIS, associated with a potentially fatal outcome, may be assumed; rT3 may be normal or elevated and is not diagnostic. An elevated TSH suggests the presence of prior hypothyroidism, which should then be treated. Finding positive antithyroid antibody titers supports the diagnosis of primary hypothyroidism but does not prove it. Use of anticonvulsants should be noted, as these agents can lower (free)T4. Dopamine used in the setting of severe illness can decrease serum TSH, contributing to persistent low TH concentrations. Hyperthyroidism is the typical cause of suppression of TSH below 0.01 µU/mL, but it is rarely difficult to exclude this diagnosis in the setting of severely depressed T4 and T3.

The question of whether interventions aimed at normalizing TH concentrations in patients with NTIS in the framework of extended critical illness are beneficial has so far not been satisfactorily answered. Only a small number of randomized controlled trials (RCTs) involving heterogeneous patient groups, ranging from critical illness at the medical ICU to heart surgery in otherwise healthy participants, have assessed the effects of treatment with THs in patients with NTIS. Both T3 and levothyroxine have been used. Overall, the RCTs of T3 or T4 in critical illness have been largely negative in terms of clinical benefit (for review, see Fliers et al.).[159] This may be partly explained by the concept that normalizing TH concentrations in serum does not equal normalizing tissue concentrations of TH. This was clearly shown in a study involving patients who were critically ill and received TH treatment. Hepatic T3 concentrations after TH treatment were disproportionally high compared with the increase in serum and muscle T3 concentrations.[78]

An unresolved and somewhat controversial issue is whether there is a place for TH treatment in patients with heart failure. Although the use of TH treatment in patients with heart failure has not been adequately studied, some trials have reported encouraging findings. A small RCT[160] in patients with dilated cardiomyopathy showed beneficial effects of medium-term (3 months) levothyroxine treatment on cardiac performance, whereas another RCT[161] showed that the TH analogue 3,5 di-iodothyropropionic acid improved some hemodynamic variables in heart failure.

An important question is whether hypothalamic neuropeptides (e.g., growth hormone-releasing hormone, growth hormone-releasing peptide 2, gonadotropin-releasing hormone, and TRH) can be used in patients with long-term critical illness in an attempt to stimulate the anterior pituitary gland, thereby restoring endocrine function in terms of plasma concentrations and hormone pulsatility.[58,162] A number of small clinical studies showed that hypothalamic neuropeptides, especially TRH in combination with growth hormone releasing peptide 2 given intravenously, restored circulating concentrations of TH and TSH pulsatility to a remarkable extent.[163] Moreover, this strategy improved bone markers and anabolic variables. These findings may point to insufficient hypothalamic drive of pituitary TSH release in protracted critical illness, which was supported by a study reporting that deceased patients with NTIS had decreased TRH mRNA expression in the hypothalamic PVN, correlating with decreased antemortem plasma TSH and T3 concentrations.[37] However, the clinical studies using hypothalamic neuropeptides in patients with protracted critical illness involved only small numbers of patients and lacked clinically significant endpoints related to morbidity and mortality.

In sum, no definitive conclusion about the effectiveness of TH treatment in patients in the ICU with NTIS can yet be made. One study in patients with acute renal failure even raised some concern about possible harm, because of a tendency towards increased mortality after treatment with levothyroxine.[164] Clearly, the reported studies so far were not adequately powered to detect clinically meaningful differences. Furthermore, most of these studies used rather high doses of either T4 or T3, probably inducing further suppression of pituitary TSH release and altered tissue deiodinase activities. In this respect, the use of neuropeptides, including TRH, to stimulate the HPT axis could be more promising. Large RCTs in well-defined patient groups will be needed to assess possible positive effects of this approach in terms of clinical outcome. High priority should be given to RCTs comparing the effect of hypothalamic neuropeptides, including TRH, with placebo, because this approach has already been shown to partly normalize concentrations of serum THs and at the same time improve metabolic markers.[165] Another theoretical possibility would be to investigate treatment with recombinant human TSH because this is a physiological stimulus—similar to TRH—for TH release from the thyroid.

KEY POINTS

- There is at present insufficient evidence that TH supplementation during NTIS is beneficial. There is a clear need for adequately powered RCTs with clinically relevant endpoints to fill this knowledge gap.

CONCLUSION

NTIS has traditionally been seen as a syndrome with lower plasma TH concentrations of unknown significance. However, it is currently clear that NTIS represents a complex set of marked and differential changes in TH physiology, both at the level of the HPT axis and at the organ level.

Whether the observed changes in critically ill patients defined as NTIS are beneficial or deleterious is currently unknown and probably depends on disease stage and severity, the need of prolonged vital support, and environmental factors including parenteral nutrition. At present, there is no evidence-based guideline supporting TH treatment of NTIS in critically ill patients. There is a clear need to perform RCTs to define whether pharmacological management of NTIS, (e.g., using neuropeptides, including TRH, may yield benefit in terms of clinical outcome).

Summary and Future Directions, 1403

INTRODUCTION

The production of thyroid hormone is an intricate process requiring multiple coordinated steps. Each step in thyroid hormone synthesis is susceptible to drug interactions, and the effects vary depending on the level of interaction (Fig. 84.1).[1] Medications affect hypothalamic-pituitary control of the thyroid, alter thyroid hormone synthesis and secretion, enhance thyroid autoimmunity, cause direct damage to the thyroid, alter protein binding to thyroid hormone, impact thyroid hormone activation, metabolism, and excretion, and diminish the absorption of thyroid hormone (Table 84.1). In addition, several common medications cause abnormal thyroid tests in euthyroid persons. Some medications interfere at multiple levels of thyroid homeostasis, which can increase the complexity of diagnosis and management. The list of medications that affect thyroid function or the interpretation of thyroid tests has grown substantially and includes prescription drugs and over-the-counter preparations (Table 84.2). Most are unintended consequences, and others have been harnessed therapeutically. This chapter will review currently known medications that interfere with thyroid hormone production, thyroid functionality, and laboratory interpretation.

DRUGS AFFECTING HYPOTHALAMIC-PITUITARY CONTROL OF THE THYROID

Metyrapone, a potent glucocorticoid inhibitor, has been shown to increase thyroid stimulating hormone (TSH), likely related to a reduction in serum cortisol. In a study of 12 healthy volunteers, metyrapone decreased morning serum cortisol by up to 47%, eliminating normal circadian variation of TSH and increasing serum TSH levels by 35% during the day, with no effect on nocturnal TSH levels.[2] TSH response to thyrotropin-releasing hormone (TRH) did not change after metyrapone administration, suggesting possible hypothalamic dysfunction as the etiology.[2]

Lithium is an alkali metal used in the treatment of bipolar affective disorders and has several effects on thyroid hormone physiology. Hypothyroidism occurs at least twice as frequently in those treated with lithium, with an annual rate of 1.5% observed in over 15 years of follow-up.[3] One metaanalysis showed a 6-fold increased risk for developing clinical hypothyroidism in lithium users.[4] The annual incidence of hypothyroidism in lithium users increases from 0.8% without thyroid antibodies to 6.4% in patients with preexisting thyroid antibodies.[3] Thyrotoxicosis also occurs more frequently in those treated with lithium.[3,5,6] This section will review the mechanism by which lithium affects the hypothalamic-pituitary-thyroid (HPT) axis. First, an exaggerated TSH response to TRH is seen in 50% to 100% of patients, and there is a significant rise in basal TSH, reflecting clinical or subclinical hypothyroidism.[5] Second, lithium concentrates in the thyroid and is a potent inhibitor of thyroid hormone release, leading to a compensatory increase in TSH concentration that may be sustained in patients with diminished thyroid reserve. Third, in rat studies lithium appears to inhibit type I (D1) and type II deiodinase 2 (D2) enzyme activity, leading to decreased triiodothyronine (T3) generation within the pituitary, further elevating TSH,[7] as well as decreased peripheral generation of T3.[5] TSH stimulation along with activation of tyrosine kinase and the Wnt/beta-catenin signaling pathways contributes to cell proliferation, resulting in goiter,[5] which is present in 5% to 59% of patients on chronic lithium therapy, depending on the population and method of detection.[8] Clinical inspection and palpation miss half of these cases compared with ultrasound, and treatment with levothyroxine (LT4) reduces the prevalence of goiter in lithium-treated patients.[9] Baseline thyroid function tests and thyroid antibodies should be performed prior to starting lithium.[7] In patients with positive antibodies, close laboratory follow-up is indicated to monitor for hypothyroidism. Fig. 84.1 Thyroid hormone physiology. Hypothalamic thyrotropin-releasing hormone (TRH) stimulates the release of thyrotropin (TSH) from pituitary thyrotrophs . This in turn stimulates the synthesis of thyroid hormone within thyroid follicles. Thyroid follicles consist of hundreds of thyrocytes surrounding a follicular lumen filled with colloid matrix. Thyroglobulin is produced in the thyrocyte and subsequently secreted into the follicular lumen. Thyroglobulin serves as the backbone for thyroid hormone synthesis in the follicle. Iodide is actively transported into the thyrocyte by the sodium-iodide symporter (NIS) and then into the follicular lumen through the anion exchange protein pendrin. In a hydrogen peroxide-dependent reaction,

thyroid peroxidase (TPO) performs several key reactions that oxidize and organify iodine, linking it to specific tyrosine residues on thyroglobulin. When two tyrosine moieties are coupled, thyroxine (T4) and triiodothyronine (T3) molecules are formed. Pinocytosis of the iodinated thyroglobulin allows lysosomal proteolysis with subsequent release of T4 and T3 into the circulation using the monocarboxylate transporter 8 (MCT8). Circulating thyroid hormone is >99% bound to carrier proteins, with thyroxine-binding globulin (TBG) accounting for approximately 70% of binding, followed by transthyretin and albumin. Local conversion of T4 to T3 at the tissue level occurs through 5′-monodeiodination of T4 by 5′-monodeiodinase type 2 (D2) and type 1 (D1). T3 binds to the thyroid hormone receptors (TR), causing a nuclear effect, which, along with its retinoid X receptor (RXR) can bind to thyroid hormone response elements (TREs). Deactivation (creation of reverse T3 from T4 and T2 from T3) also occurs at the tissue level through the actions of 5′monodeiodination type 3 (D3). Pituitary T3 is obtained from both systemic circulation and intrapituitary D2, which then provides feedback to the hypothalamus and pituitary. Thyroid hormone disposal is primarily performed through successive deiodination and conjugation, including glucuronidation and sulfation in the liver and kidney. These actions increase water solubility and subsequent secretion into the bile. Glucuronidated thyroid hormone can be eliminated in feces or recycled in the enterohepatic circulation.

TABLE 84.1 Classification of Drug Effects on the Thyroid

- Drugs affecting hypothalamic-pituitary control of the thyroid
- Drugs affecting thyroid hormone synthesis or secretion
- Drugs that enhance thyroid autoimmunity
- Drugs causing direct thyroid damage
- Drugs affecting protein binding of thyroid hormone
  - Changes in binding proteins
  - Displacement of thyroid hormone from binding proteins
- Drugs affecting thyroid hormone activation, metabolism, and excretion
  - Thyroxine-to-triiodothyronine conversion
  - Thyroid hormone metabolism
  - Disposal of thyroid hormone
- Drugs affecting the absorption of thyroid hormone preparations
- Drugs causing abnormal thyroid testing in euthyroid patients
- The effect of thyroid dysfunction on drug metabolism

hypothyroidism develops, thyroid supplementation can be initiated without the need to stop lithium.[5,7,8]

Opiates decrease basal TSH and the TSH response to TRH, while T3 and thyroxine (T4) concentrations typically remain unchanged with chronic opiate use.[10]

Immune checkpoint inhibitors (ICIs) regulate immune response by modulating T-cell antitumor activity. There are three main ICI categories, including cytotoxic T-lymphocyte antigen 4 (CTLA-4), programmed cell death-1 (PD-1), and programmed cell death-ligand 1 (PD-L1) inhibitors. CTLA-4 inhibitors are primarily used to treat malignant melanoma, and PD-1 inhibitors are used in the treatment of various solid tumors. Multiple endocrine toxicities are seen with use of ICI medications; here, we will discuss hypophysitis resulting in central thyroid dysfunction. Enhanced thyroid autoimmunity and destructive thyroiditis will be discussed later in the chapter.

Hypophysitis leading to central hypothyroidism is a serious side effect of ICI therapy and occurs most frequently with combination therapy (CTLA-4/PD-1 or PD-L1 blockade). Monotherapy with CTLA-4 inhibitors, specifically ipilimumab, has also been associated with destructive hypophysitis in 10% or more of patients treated.[1] This side effect is rarely seen with PD-1/PD-L1 inhibitor monotherapy, where the incidence is less than 0.6%.[11] The precise mechanism of destructive hypophysitis remains to be elucidated.[12] A review by Byun et al. found an overall incidence of hypophysitis in 9.1% using strict criteria for excluding primary dysfunction, but reports have ranged from 0.4% to 17%, with a higher incidence in men compared with women (15.6% vs. 3.6%).[11] Decreasing TSH levels may be an early sign of impending hypophysitis.[13] Among 184 patients developing hypophysitis during ICI therapy, the incidence of secondary hypothyroidism was 7.6% within the first 4 to 16 weeks of therapy.[11] Thyroid labs will show a normal TSH with low thyroid hormones, which can be confused with non-thyroidal illness (NTI). As a result, clinical and hormonal monitoring are critical prior to and throughout ICI therapy. Immunotherapy is not usually stopped with the discovery of hypophysitis, but has occasionally been delayed.[13] Thyroid function recovers in approximately 50% to 60% of patients after months to years following discontinuation of therapy.[12,13] Recovery rates are highest with longer periods of follow-up.[13]

KEY POINTS: Immune Checkpoint Inhibitors (anti-CTLA-4, PD-1, PD-L1)

- Hypophysitis leading to central hypothyroidism is a serious side effect of immune checkpoint inhibitor (ICI) therapy.
- Decreasing thyroid-stimulating hormone (TSH) levels may be an early sign of impending hypophysitis.
- Thyroid function recovers in approximately 50%–60% of patients after months to years following discontinuation of therapy.
- Primary thyroid dysfunction occurs in 5%–10% of patients treated with CTLA-4 inhibitors, 10%–20% treated with PD-1 inhibitors, and >20% treated with combination therapy.
- Destructive thyroiditis is treated with LT4 without interruption in ICI therapy. Preexisting thyroid antibodies increase the risk of developing thyroid dysfunction.

Dopaminergic agents have an inhibitory effect on TSH secretion.[14] Dopamine infusion at a dose of 4 ug/kg has been shown to suppress mean TSH levels and TSH pulse amplitude by 70%.[15] Studies in critically ill adults requiring dopamine infusions show a suppressive effect on the HPT axis that may be superimposed upon changes due to NTI.[16] Dopamine agonist therapy, with bromocriptine or cabergoline, has also been examined in this regard. In a study of 17 obese women treated with bromocriptine compared to placebo, both pulsatile and nonpulsatile TSH secretion was decreased, but free T4 (FT4) and total T3 (TT3) concentrations did not change.[17] Conversely, in a study of nine patients with prolactinomas treated with cabergoline, significant reductions in T4 and T3 levels were reported, with a slight but insignificant decrease in TSH.[18] Two of the nine patients in this study required LT4 treatment based on symptoms and low T4 levels.[18] Considering these results, the inhibition of TSH secretion with dopamine agonist therapy is variable, often clinically insignificant, and likely related to the dose and specific medication.

Data on the effect of the dopamine antagonist metoclopramide on TSH secretion is conflicting. In a study of 11 healthy volunteers treated with intravenous (IV) metoclopramide, 24-hour mean TSH levels were found to be increased.[19] However, in another study of 17 women treated with oral metoclopramide, plasma TSH and thyroid hormone levels did not change.[20]

TABLE 84.2 **Drugs Influencing Endogenous Thyroid Function**

Representative Drug	Drug Class	Nature of Interaction	Severity Grade[1]	Suggested Monitoring Interval[2] or Comment
Drugs Affecting Hypothalamic-Pituitary Control of the Thyroid				
Metyrapone	11-beta-hydroxylase inhibitor	TSH increase	1	None or annually
Lithium	Element	TSH increase	1–2	Quarterly
Opiates	Opioids	TSH decrease	1	None
Ipilimumab Tremelimumab	Anti-CTLA-4, Immune checkpoint inhibitors	Hypophysitis	3–5	Monthly or with each cycle
Bromocriptine	Dopamine agonists	TSH suppression	1	None or annually
Metoclopromide	Dopamine antagonist	TSH increased or normal	1	None
Octreotide	Somatostatin analogs	TSH suppression	1	None or annually
Dobutamine	Inotrope	TSH suppression	1	None
Bexarotene	Retinoid	Central hypothyroidism	3–4	Monthly
Mitotane	Adrenolytic agent	TSH suppression	2	Quarterly
Dexamethasone Hydrocortisone Methylprednisolone	Glucocorticoids	TRH/TSH suppression	1–2	None or monthly x 1
Metformin	Biguanide	TSH suppression	1	None or annually
Drugs Affecting Thyroid Hormone Synthesis or Secretion				
Iodine	Micronutrient	Decreased TH synthesis Iodine-induced hyperthyroidism	1–4	None or quarterly x 1
Amiodarone	Class III antiarrhythmic	Decreased TH synthesis Iodine-induced hyperthyroidism	2–5	Semiannually
Lithium	Element	Decreased TH release	1–2	Quarterly
Aminoglutethimide	Steroidogenesis inhibitor	Decreased TH synthesis	1–2 (dose-dependent)	Periodically with high doses
Sunitinib	Tyrosine kinase inhibitor	Impairs cellular uptake of TH by MCT8 inhibition	3–5	Quarterly
Drugs that Enhance Thyroid Autoimmunity				
Alemtuzumab	Anti-CD52	*De novo* development of thyroid antibodies	3–4	Semiannually
Ipilimumab Nivolumab	Immune checkpoint inhibitors	Reduction in immune self-tolerance	3–5	Monthly or with each cycle
Interferon-α Interleukin-2	Cytokine	*De novo* development of thyroid antibodies	2	Semiannually
Drugs Causing Direct Thyroid Damage				
Amiodarone	Class III antiarrhythmic	Direct cytotoxicity	3–5	Quarterly to semiannually
Nivolumab Pembrolizumab	Anti-PD-1, Immune checkpoint inhibitors	Immune thyroiditis	3–5	Monthly or with each cycle
Interleukin-2	Cytokine	Immune thyroiditis	2	Semiannually
Interferon-α	Cytokine	Immune thyroiditis	2	Semiannually
Sunitinib Sorafenib	Tyrosine kinase inhibitor	Immune thyroiditis	3–5	Quarterly
Lithium	Element	Thyroiditis, unknown association	1–2	Quarterly
Drugs Affecting Protein Binding of Thyroid Hormone				
Changes in Binding Proteins				
Oral estrogen	Sex steroid	Increased thyroxine-binding globulin	2	None (unless taking thyroid hormone)
Tamoxifen Raloxifene	Selective estrogen receptor modulator	Increased thyroxine-binding globulin	1	None (unless taking thyroid hormone)
Heroin Methadone	Opioids	Increased thyroxine-binding globulin	1	None
Mitotane	Adrenolytic agent	Increased thyroxine-binding globulin	1	None
5-Fluorouracil	Antimetabolite	Increased thyroxine-binding globulin	1	None (unless taking thyroid hormone)

TABLE 84.2 Drugs Influencing Endogenous Thyroid Function—cont'd

Representative Drug	Drug Class	Nature of Interaction	Severity Grade[1]	Suggested Monitoring Interval[2] or Comment
Oral androgen	Sex steroid	Decreased thyroxine-binding globulin	1	None (unless taking thyroid hormone)
Danazol	Synthetic steroid	Decreased thyroxine-binding globulin	1	None
Oral glucocorticoids	Glucocorticoids	Decreased thyroxine-binding globulin	1–2	None or monthly x 1
Niacin	Vitamin B3	Decreased thyroxine-binding globulin	1	None
Displacement of Thyroid Hormone from Binding Proteins				
Phenytoin Carbamazepine	Antiepileptic	Laboratory changes	1–2	Annually
Salsalate Fenclofenac	Nonsteroidal antiinflammatory	Laboratory changes	1	None
Furosemide	Loop diuretic	High dose only	1	None
Drugs Affecting Thyroid Hormone Activation, Metabolism and Excretion				
Drugs that inhibit T4 toT3 conversion				
Amiodarone	Class III antiarrhythmic	Laboratory changes	2 (Note: greater severity in other types of interaction)	Semiannually
Propranolol Metoprolol Atenolol	Beta-adrenergic blocker	Reduced T3 (high dose only)	1	None
Dexamethasone	Glucocorticoid	Reduced T3	2	None or monthly x 1
Drugs that Affect Thyroid Hormone Metabolism				
Phenobarbital Phenytoin Carbamazepine	Antiepileptic	Increased hepatic conjugation	1	Annually
Rifampin	Antimicrobial	Increased hepatic conjugation	1	Annually
Imatinib Motesanib Sorafenib Sunitinib Vandetanib	Tyrosine kinase inhibitor	Increased type 3 deiodinase activity	2	Quarterly
Bexarotene	Retinoid	Increased sulfation	2 (Note: greater severity in other types of interaction)	Monthly
Drugs Affecting Disposal of Thyroid Hormone				
Cholestyramine Colestipol Colesevelam	Bile acid sequestrant	Decreased enterohepatic recycling	1–2	None
Drugs Affecting the Absorption of Thyroid Hormone Preparations				
Iron sulfate	Mineral	Decreased absorption	1–2	Consider repeating labs 4 weeks after starting or stopping
Calcium carbonate	Antacid, supplement	Decreased absorption	1–2	Consider repeating labs 4 weeks after starting or stopping
Aluminum hydroxide	Antacid	Decreased absorption	1–2	Consider repeating labs 4 weeks after starting or stopping
Cholestyramine Colesevelam Colestipol	Bile acid sequestrant	Decreased absorption and reduced enterohepatic recycling	1–2	Consider repeating labs 4 weeks after starting or stopping
Sucralfate	Sucrose sulfate-aluminum complex	Decreased absorption	1–2	Consider repeating labs 4 weeks after starting or stopping

Continued

TABLE 84.2 Drugs Influencing Endogenous Thyroid Function—cont'd

Representative Drug	Drug Class	Nature of Interaction	Severity Grade[1]	Suggested Monitoring Interval[2] or Comment
Raloxifene	Selective estrogen receptor modulator	Decreased absorption	1–2	Consider repeating labs 4 weeks after starting or stopping
Lansoprazole Omeprazole	Protein pump inhibitor	Decreased pill dissolution	1–2	Consider repeating labs 4 weeks after starting or stopping
Drugs Causing Abnormal Thyroid Testing in Euthyroid Patients				
Biotin	Vitamin B7	Laboratory Changes	1	None
Amiodarone	Class III antiarrhythmic	Laboratory changes	1	None
Phenytoin Carbamazepine	Antiepileptic	Laboratory changes	1	None
Salsalate	Nonsteroidal antiinflammatory	Laboratory Changes	1	None
Heparin	Anticoagulant	Laboratory Changes	1	None
The Effect of Thyroid Dysfunction on Drug Metabolism				
Warfarin	Anticoagulant	Hyperthyroidism increases catabolism of vitamin K–dependent clotting factors, prolonging PT	3–5	Dose may need to be decreased in hyperthyroid patients
Digoxin	Cardiac glycoside	Enhanced (hyperthyroidism) or delayed (hypothyroidism) clearance of medication	3–5	Dose may need to be adjusted in hyperthyroid or hypothyroid patients
Acetaminophen	Analgesic	Increased absorption, earlier peak, more rapid decrease with hyperthyroidism	1	Dose may need to be adjusted in hyperthyroid patients
Propranolol	Beta-blocker	Hepatic first-pass metabolism increased (hyperthyroidism) or decreased (hypothyroidism)	1	Dose may need to be adjusted in hyperthyroid patients
Glucocorticoids	Glucocorticoid	Hepatic clearance increased (hyperthyroidism) or decreased (hypothyroidism)	1–4	Increased metabolism of corticosteroids during thyrotoxicosis could precipitate adrenal crisis in a patient dependent on adrenal replacement therapy/ patients with borderline adrenal function
Statin medications	Statin	Increased risk of adverse events in hypothyroidism (myalgias, myositis, rhabdomyolysis)	1–3	Ensure patient is euthyroid prior to starting or increasing statin dose

[1] Severity grade: Adapted from *National Cancer Institute Common Terminology Criteria for Adverse Events v5.0*. 27 Nov. 2017, ctep.cancer.gov/protocoldevelopment/electronic_applications/docs/CTCAE_v5_Quick_Reference_8.5x11.pdf.
Grade 1, mild: asymptomatic or mild symptoms; clinical or diagnostic observation only; intervention not generally indicated.
Grade 2, moderate: intervention indicated, potentially limiting activities of daily living.
Grade 3, severe: medically significant but generally not immediately life-threatening; potentially requiring hospitalization or prolongation of hospitalization.
Grade 4, life-threatening consequences: urgent intervention required.
Grade 5, death related to adverse event.

[2] Monitoring intervals are based on the timing, frequency, and severity (grade) of the drug interaction. When available, data were derived from clinical practice guidelines.

TSH, Thyroid-stimulating hormone; *CTLA-4*, cytotoxic T-lymphocyte-associated protein; *TRH*, thyrotropin-releasing hormone; *TH*, thyroid hormone; *PD-1*, programmed cell death protein 1; *T3*, triiodothyronine; *T4*, thyroxine; *LT4*, levothyroxine; *MCT8*, monocarboxylate transporter 8.

(From Ross DS, Burch HB, Cooper DS, et al. 2016 American Thyroid Association guidelines for diagnosis and management of hyperthyroidism and other causes of thyrotoxicosis. *Thyroid*. 2016;26:1343–1421.)

Somatostatin analogs bind to multiple receptors on pituitary cells and directly affect hormone secretion. The effects on thyroid function appear to depend on the duration of treatment. Administration of somatostatin to healthy volunteers resulted in decreased serum TSH pulse frequency and amplitude.[21] In a study of 25 patients with acromegaly started on octreotide, transient acute changes occurred, including decreased TSH response to TRH and a subsequent decrease in T3 levels, but these changes reverted to baseline during continued therapy.[22] In summary, somatostatin analogs directly suppress TSH through direct effects on pituitary thyrotrophs, but the effects are transient and do not appear to cause clinically significant central hypothyroidism.

Dobutamine is an inotrope that acts on cardiac β1-adrenergic receptors and weakly on peripheral β2- and α-receptors. Clinically, this agent is used for the treatment of congestive heart failure to increase cardiac output. Dobutamine doses of 5 μg/kg/minute or less do not affect TSH levels,[23] but higher doses are associated with a small but significant decrease in TSH, detectable within 15 minutes and persisting for 15 minutes after drug discontinuation.[24] Dobutamine infusion has also been shown to increase FT3 levels in patients with decompensated heart failure, which may be in part related to a reversal of the acute effects of NTI by treating the underlying disorder. For example, after an improvement in hemodynamic status with dobutamine, all patients had improvement in low T3, with 42% attaining normal T3 levels.[25]

Bexarotene is a vitamin A analog specific to rexinoid receptors and used in the treatment of T-cell lymphomas. Bexarotene causes a rapid suppression of TSH, leading to central hypothyroidism in 40% to 70% of patients, in a dose-related fashion.[26,27] This effect is likely related to direct effects on pituitary thyrotrophs, as well as by enhanced thyroid hormone metabolism through nondeiodinase pathways,[28] which will be discussed later in this chapter. Normal thyroid function generally returns after bexarotene discontinuation.[29] Isotretinoin therapy in acne vulgaris patients has been examined for similar effects, but only minor and clinically insignificant changes in TSH, T3, and T4 levels were observed.[30]

Mitotane is a synthetic derivative of the insecticide dichlorodiphenyltrichloroethane with adrenolytic properties that result in impaired steroidogenesis. It is used to treat adrenocortical carcinoma. Mitotane can cause both primary and secondary thyroid dysfunction. Central hypothyroidism is usually seen in the first 3 months of therapy with a normal TSH, impaired TSH response to TRH, and low FT4. Free T3 (FT3) generally remains normal. FT4 reductions are inversely proportional to mitotane concentration.[31] Long-term LT4 replacement is often required.[32] Mitotane may also increase thyroxine-binding globulin (TBG) and competes with T4 for TBG binding sites. The precise etiology of central hypothyroidism in this setting is currently unknown.[31]

Glucocorticoids have multiple effects on the thyroid gland, which will be discussed throughout this chapter. Here, we will discuss the effects on the HPT axis. TSH secretion is inhibited by both physiologic and therapeutic glucocorticoid administration.[2,33] Higher doses of hydrocortisone eliminate the nocturnal TSH surge, reduce 24-hour TSH secretion, and decrease the pulse amplitude of TSH release, with minimal changes in T4 levels.[33] Dexamethasone has been shown to reduce TSH in a dose-dependent fashion.[34,35] In one study, older individuals required higher doses of dexamethasone to inhibit the TSH response to TRH than that seen in younger research participants.[35] Overall, the potency, dose, and route of administration of glucocorticoid influence the magnitude of the effect on thyrotrophs. Importantly, chronic high-dose glucocorticoid or other causes of Cushing syndrome do not appear to cause clinically evident central hypothyroidism or require thyroid hormone supplementation.[34]

Metformin was found to reduce TSH in patients with overt and subclinical hypothyroidism, but not in euthyroid patients.[36,37] The suppressive effect on TSH is possibly due to inhibitory action of metformin on AMP-activated protein kinase in the hypothalamus, as well as other potential mechanisms.[38] No metformin-related changes in absorption of thyroid hormone have been found.[39] Thyroid hormone levels are unchanged, and although the TSH decrease is statistically significant, it does not suppress to levels that would be concerning for central hypothyroidism.[38]

DRUGS AFFECTING THYROID HORMONE SYNTHESIS OR SECRETION

Iodine is a trace element that is required for thyroid hormone synthesis. A daily intake of 150 μg is recommended by the World Health Organization for all nonpregnant or lactating adults. However, many prescriptions, over-the-counter supplements, topical agents, and foods contain iodine concentrations that far exceed the daily recommended intake. Examples are amiodarone, expectorants/vaginal douches, povidone iodine, and kelp.[40] The physiologic response to iodine excess is inhibition of thyroid peroxidase enzyme activity, which results in decreased synthesis of thyroid hormone. This phenomenon is known as the Wolff–Chaikoff effect. In a normal thyroid gland, regulatory mechanisms exist to maintain a euthyroid state despite wide fluctuations in iodine intake. A healthy thyroid gland will escape the Wolff–Chaikoff effect and resume hormone synthesis within days by decreasing the expression of sodium-iodide symporter, thus limiting the influx of iodine into the thyroid. However, patients with decreased thyroid reserve, as occurs with chronic thyroiditis, partial thyroidectomy, or thyroid irradiation, are unable to escape the Wolff–Chaikoff effect, which can result in a more prolonged period of hypothyroidism. Patients who have underlying thyroid autonomy, such as those with toxic adenoma or toxic multinodular goiter, are susceptible to iodine-induced hyperthyroidism, a phenomenon known as Jod-Basedow.

Amiodarone's effects on the thyroid can be classified as either iodine-related effects or intrinsic drug effects. Intrinsic amiodarone drug effects include disruption of thyroid hormone synthesis, direct damage to thyroid follicular cells, and inhibition of both peripheral and central monodeiodination. Additionally, amiodarone and its metabolites have structural similarities to T3 and T4, allowing them to potentially interact with thyroid hormone receptors.[41] Finally, there are acute and chronic effects on thyroid function laboratory testing in amiodarone-treated patients who remain euthyroid.[42] Intrinsic drug effects will be discussed later in the chapter; here we will focus on the iodine-related effects. Fig. 84.2 shows the direction of thyroid laboratory changes in euthyroid, thyrotoxic, and hypothyroid patients treated with amiodarone.

Amiodarone is classified as a class III antiarrhythmic (a potassium channel blocker), but also has some class I, II, and IV effects by affecting sodium, β-adrenergic, and calcium channels making it a very potent antiarrhythmic.[41] The drug has a long (>100-day) half-life, mainly due to accumulation in adipose tissue, but can also accumulate in the liver, lung, muscle, and thyroid. A 200-mg dose releases 75 mg of organic iodine, leading to the release of approximately 6 to 7 mg of free iodine into the circulation. This is 30 to 45 times greater than the average American daily dietary intake (150–200 mcg).[41,42] As such, amiodarone can cause both iodine-induced hypothyroidism and hyperthyroidism through mechanisms described earlier in this chapter for iodine. Predictors of amiodarone-induced thyroid dysfunction include female sex, preexisting autoimmune thyroiditis, and nodular thyroid disease.[41]

Amiodarone-induced hypothyroidism (AIH) is more common in areas of iodine deficiency than regions of iodine sufficiency, and the reverse is true with amiodarone-induced thyrotoxicosis (AIT). AIH occurred in 22% of amiodarone patients in Worcester, Massachusetts but only 5% of those from the low-iodine region of Tuscany, Italy.[43] Conversely, AIT occurred in 9.6% of amiodarone-treated patients in Tuscany, but only 2% in Worcester.[43] AIH can occur in patients without underlying thyroid disease but is generally seen in patients with diminished thyroid reserve who are unable to escape the Wolff–Chaikoff effect. Patients with AIH present with elevated TSH and a low FT4 levels, signifying primary hypothyroidism. Hypothyroidism in this setting is easily addressed with thyroid hormone replacement therapy, and therefore amiodarone does not need to be discontinued.[41]

Iodine-induced hyperthyroidism in patients taking amiodarone is referred to as type-1 amiodarone-induced thyrotoxicosis (AIT1). Amiodarone can have direct toxic effects on thyrocytes, leading to a destructive thyroiditis, known as type 2 amiodarone-induced thyrotoxicosis (AIT2), which will be discussed later in this chapter. AIT1 is diagnosed in patients presenting with a suppressed TSH and elevated levels of T4 and T3.

Euthyroid	Hyperthyroid	Hypothyroid
↑ Free T4	↑ Free T4	↓ Free T4
↑ TSH (typically <10 mU/L and transient)	↓ TSH (undetectable)	↑ TSH (typically >10)
↓ Total T3	↑ Total T3	↓ Total T3
	+/– Antithyroid antibodies	+ Antithyroid antibodies

Fig. 84.2 **Amiodarone can cause thyroid test abnormalities in a euthyroid person or induce clinical hyperthyroidism (AIT) or hypothyroidism (AIH).** The figure shows the expected thyroid test results in each of these situations. Amiodarone can induce thyrotoxicosis with two classical variants, AIT1 and AIT2. Often, however, these two variants overlap, and diagnostic uncertainty can exist. AIT1 is due to the iodine-related effects of amiodarone and often occurs in patients with underlying thyroid autonomy, such as toxic multinodular goiter or Graves disease. AIT2 occurs due to the intrinsic effects of amiodarone that cause direct damage to the thyroid. This often occurs in patients without a prior history of thyroid abnormality. AIH occurs due to the iodine-related effects of amiodarone and occurs most commonly in individuals with underlying chronic thyroiditis.

Treatment of AIT1 is directed at controlling increased thyroid hormone synthesis using thionamides, and occasionally potassium perchlorate. Definitive therapy for the underlying disease process is recommended after achieving a euthyroid state, particularly in those for whom continued amiodarone therapy is required. In patients with mixed AIT1 and AIT2 or indeterminate features, both glucocorticoids and methimazole are recommended, particularly if underlying cardiovascular compromise is present.[44] In a small subset of patients with rapid clinical deterioration who are unresponsive to medical therapy, total thyroidectomy may be required to achieve a euthyroid status.[41]

Lithium accumulates in thyroid tissue, leading to concentrations three to four times that of plasma. Lithium decreases release of thyroid hormone from the thyroid, most likely through disruption of effective pinocytosis.[5] The ability of lithium to increase iodine retention has been utilized as adjunctive therapy to radioiodine to both maximize delivery of radioactive iodine to the thyroid or thyroid cancer and to limit whole-body radiation dose; however, it is rarely practical to do so. Lithium has also been purported to decrease the risk of aggravation of thyrotoxicosis in the first 1 to 2 weeks after radioiodine therapy for Graves disease.[45] Current American Thyroid Association guidelines state that there is insufficient evidence to support the use of lithium as adjunctive therapy to radioiodine for either benign or malignant thyroid disease.[44,46]

In addition to alteration of iodine retention by the thyroid, lithium affects thyroid hormone synthesis through a number of additional mechanisms, including interference with tyrosine iodination, alteration of thyroglobulin structure, and inhibition of colloid formation.[7,8] As a result of these antithyroid properties, lithium has been utilized in the treatment of thyrotoxicosis.[47] Lithium use in this setting is reserved for thyrotoxic individuals who do not tolerate or respond to thionamides. The typical doses required are relatively low, such as 750 mg per day,[5] but monitoring of lithium levels is required to avoid toxicity.

Aminoglutethimide, a steroidogenesis inhibitor, blocks multiple CYP enzymes, resulting in inhibition of both androgen and corticosteroid synthesis. It has typically been used for treatment of Cushing syndrome, adrenal malignancy, and breast and prostate cancer. Aminoglutethimide was previously used as an anticonvulsant but was withdrawn from the market due to adverse effects, including goiter and clinical hypothyroidism in children. This drug induces hypothyroidism through inhibition of T4 synthesis, with a compensatory increase in TSH.[48] This effect appears to be dose-dependent. Daily doses of 250 mg or less have minimal effects on thyroid function, but doses of 1000 mg/day, as have been used to treat prostate cancer, cause marked TSH elevation in approximately 31% of patients.[49] These patients are clinically hypothyroid and require LT4 replacement therapy.

Tyrosine kinase inhibitors (TKIs) are proteins developed as chemotherapy agents to block ATP-binding sites on tyrosine kinase receptors, causing inhibition of signal transduction. The result is alteration of multiple tumor cell processes, including cell proliferation, survival, invasiveness, and angiogenesis, depending on the target. Although the predominant etiology of TKI-induced thyroid dysfunction occurs through destructive thyroiditis and effects on hepatic metabolism (discussed later in the chapter), these drugs also impair cellular uptake of thyroid hormone by inhibiting monocarboxylate transporter 8 (MCT8). This leads to a reduced supply of T3 to peripheral and central cells.[50]

DRUGS THAT ENHANCE THYROID AUTOIMMUNITY

Alemtuzumab, a monoclonal antibody targeting CD52 cell surface markers on lymphocytes and monocytes, is commonly used in the treatment of multiple sclerosis (MS), leukemia, and rheumatoid arthritis. Interestingly, thyroid dysfunction occurs when alemtuzumab is used in the treatment of MS,[51,52] but not when used in the treatment of leukemia[53] or rheumatoid arthritis.[54] In one study, 73 of 216 (33.8%) alemtuzumab-treated patients with MS developed thyroid dysfunction, and among those 65.8% (22.2% overall) developed Graves disease.[51] At baseline, 11 of 73 (15.1%) were thyroid peroxidase (TPO) antibody-positive, and 40 of 73 (54.8%) developed TPO antibody positivity *de novo*.[51] In another study, 102 of 248 (41.1%) patients with MS treated with alemtuzumab developed thyroid dysfunction, and among those 71.6% (29.4% overall) developed Graves disease.[52] The median interval between the final alemtuzumab dose and the onset of Graves disease was 17 months[52]; however, Graves disease associated with alemtuzumab has occurred up to 9 years following completion of therapy.[51,52] Patients with MS treated with alemtuzumab may less commonly develop destructive thyroiditis and hypothyroidism. Spontaneous resolution of overt thyrotoxicosis due to Graves disease occurred in 36.7% of alemtuzumab-treated patients, while resolution of overt hypothyroidism occurred in 17.4% in one study.[51] Smoking, family history of autoimmune disease, and positive pretreatment TPO antibodies are risk factors for developing thyroid dysfunction in patients with MS treated with alemtuzumab.[51,52]

KEY POINTS: Alemtuzumab

- Thyroid dysfunction has been shown to occur when alemtuzumab is used in the treatment of multiple sclerosis (MS).
- The most common thyroid manifestation is Graves disease, but destructive thyroiditis and hypothyroidism may also occur.
- Smoking, family history of autoimmune disease, and positive pretreatment thyroid peroxidase antibodies are risk factors for developing thyroid dysfunction in patients with MS treated with alemtuzumab.

ICIs, including CTLA-4 inhibitors and PD-1 inhibitors, are designed to promote immune system eradication of cancer cells, but also increase the risk of autoimmunity. Primary thyroid dysfunction during immune checkpoint blockade is believed to result from a reduction in immune self-tolerance caused by these drugs.[55,56] In 40% to 50% of affected patients, TPO or thyroglobulin antibodies are present at the time of thyroid disruption,[57,58] but their pathophysiological role is unknown, as most series do not include pretreatment antibody levels. Some studies show increases in preexisting antibodies[59,60] or antibody development[61] during immune checkpoint blockade. Positive pretreatment thyroid antibodies increase the risk of drug-induced thyroid dysfunction.[59,61] Destructive thyroiditis related to immune checkpoint blockade is discussed later in this chapter.

Cytokine therapy. *De novo* development of thyroid antibodies has occurred during therapy with the cytokines interleukin-2 (IL-2) and interferon-α (IFN-α). IL-2 is a T-cell growth factor that acts to promote CD8 and natural killer cell activity[62] and is used in the treatment of metastatic melanoma and renal cell carcinoma. In a series of 89 patients being treated with IL-2, *de novo* development of thyroid antibodies occurred in 11 of 18 (61%) patients with negative antibodies before treatment, including six who became transiently positive and five who became permanently positive.[63]

Approximately 5% to 15% of patients using IFN-α develop clinical autoimmune thyroid disease, as part of a larger number developing thyroid antibodies without clinical dysfunction.[64] In one systemic review, studies providing sufficient data to calculate the incidence of *de novo* development of thyroid antibodies showed that this occurred in 135 of 825 (16.4%) patients treated with IFN-α.[65] These antibodies can develop during or after completion of therapy and may persist long term. In one report, 72% of patients developing thyroid antibodies during treatment with IFN-α continued to have positive antibodies at a median of 6.2 years of follow-up after completing therapy.[66] Cytokine therapy causing destructive thyroiditis is discussed in the next section of this chapter.

DRUGS CAUSING DIRECT THYROID DAMAGE

Amiodarone also causes destructive thyroiditis in 5% to 10% of individuals without underlying thyroid disease, a complication known as AIT2. AIT2 has been postulated to result from the proapoptotic and cytotoxic effects of amiodarone and its main metabolite desethylamiodarone. As with other forms of thyroiditis, the thyrotoxic phase results from leakage of preformed hormone into circulation after direct follicular cell damage, followed by a hypothyroid phase before full or partial recovery. Those with preexisting diminished thyroid reserve, such as occurs with chronic lymphocytic thyroiditis, may not achieve full recovery and will require thyroid supplementation.[41,42] Differentiating between AIT1 and AIT2 is challenging, and indeterminate forms may have overlapping features.[44] In general, AIT1 occurs in individuals with underlying thyroid disease such as toxic nodules or Graves disease. On exam, a goiter may be present with increased vascularity seen on Doppler flow ultrasonography. Conversely, patients with AIT2 often have normal or decreased blood flow to the thyroid. Iodine uptake measurements may be increased with AIT1, but published results are conflicting. ^{99m}Tc-sestamibi scanning may help to differentiate AIT1 from AIT2, with increased uptake in those with AIT1 and low or absent in AIT2.[67,68] Mixed or indeterminate AIT has been considered in those with persistent uptake or rapid washout of tracer.[41,42]

Under ideal circumstances, AIT1 would be treated with methimazole, and AIT2 would be treated with glucocorticoids. Given frequent diagnostic uncertainty, the following management approach has been recommended by the American Thyroid Association.[44] Patients presenting with AIT should first be evaluated for definite evidence of underlying thyroid disease that would suggest AIT1, such as Graves disease or toxic multinodular goiter. If these etiologies are present, and the patient is without evidence of acute cardiovascular compromise, the patient should be treated initially with methimazole alone. In patients presenting with cardiovascular compromise, combination therapy with methimazole and glucocorticoids should be started immediately in order to avoid delay in the delivery of appropriate therapy resulting from possible misclassification. For most patients without evidence of underlying Graves disease or toxic nodular disease and without initial cardiovascular compromise, glucocorticoid therapy should be the initial therapy. Treatment is targeted at reducing the inflammatory process with moderate doses of oral glucocorticoids such as prednisone 0.5mg/kg/day. Discontinuation of amiodarone is often considered but not absolutely required, particularly if it is the only antiarrhythmic therapy showing efficacy in the patient under evaluation. Rapid improvement in AIT2 can occur within 1 to 2 weeks after starting glucocorticoids, with 60% of patients in one study returning to a euthyroid state within 30 days, although 16% required more than 90 days for resolution.[69] Patients failing to respond rapidly to corticosteroid therapy often have methimazole added to their corticosteroid regimen.[44] In patients who are refractory to all medical therapy, total thyroidectomy is occasionally required to rapidly restore euthyroidism,[41,42] but this group of patients is at increased risk of perioperative complications.[70] Approximately 80% of patients with AIT2 have spontaneous restoration of euthyroidism; the remainder develop prolonged or permanent hypothyroidism.[41,69]

KEY POINTS: Amiodarone

- Amiodarone causes expected changes in thyroid tests in euthyroid persons (Figure 2).
- Amiodarone can induce both thyrotoxicosis (amiodarone-induced thyrotoxicosis type 1 [AIT1] and amiodarone-induced thyrotoxicosis type 1 [AIT2]) and hypothyroidism (amiodarone-induced hypothyroidism [AIH]).
- Amiodarone-induced thyrotoxicosis can be difficult to manage due to frequent diagnostic uncertainty.
- If AIT1 is suspected (underlying Graves disease [GD] or toxic multinodular goiter [TMNG]) and no evidence of cardiovascular compromise: treat initially with antithyroid drugs (ATDs) alone.
- If AIT2 is suspected (no underlying GD or TMNG) and no evidence of cardiovascular compromise: treat initially with glucocorticoid therapy alone.
- In patients presenting with cardiovascular compromise: ATDs and glucocorticoids should be started immediately to avoid delay in therapy from possible misclassification.

ICIs. Thyroid dysfunction is noted in approximately 5% to 10% of patients treated with CTLA-4 inhibitors, 10% to 20% of those treated with PD-1 inhibitors, and more than 20% of patients treated with combination therapy.[1] Patients typically present with painless thyroiditis, manifested by transient thyrotoxicosis followed by hypothyroidism; Graves disease rarely occurs. Thyrotoxicosis commonly occurs 4 to 8 weeks after the start of therapy[71] but may occur in the first 1 to 2 weeks with combination therapy[71-73] or by 18 weeks with CTLA-4 inhibitor monotherapy.[72] The thyrotoxic phase is often mild and may be overlooked, resolving in 3 to 10 weeks,[72] but severe cases have occurred.[74] Hypothyroidism follows at 10 to 20 weeks after the initiation of therapy[58] and is frequently irreversible.[58,75] Immune checkpoint blockade therapy is generally not stopped as a result of adverse thyroid effects,[72] which are managed conventionally.[44,76]

Lithium has been associated with painless thyroiditis.[6] Although the nature of this association is unknown, approximately half of affected patients have positive tests for thyroid antibodies.[6] Conservative treatment with beta-blockers is typically the treatment of choice.

Cytokine Therapies IL-2. Thyroid dysfunction, generally resulting from destructive thyroiditis, is a common complication of IL-2 therapy that is seen in 15% to 50% of patients treated.[1] In a series of 89 patients with solid tumors treated with IL-2, 22% developed thyroid dysfunction, presenting with mild thyrotoxicosis at a median of 7 weeks, followed by hypothyroidism at a median of 11 weeks.[63] TSH receptor antibodies are negative, and radioactive iodine uptake and scan shows a low iodine uptake.[77] Ultrasound shows diffuse hypoechogenicity with normal or reduced vascularity, consistent with destructive thyroiditis.[64] Fine-needle aspiration in such patients has shown infiltration by lymphocytes, plasma cells, and histiocytes, indicative of thyroiditis. Thyrotoxicosis is typically mild and requires only symptomatic treatment. Subsequent hypothyroidism is usually self-limited, with only the minority of patients requiring LT4 supplementation. It is controversial whether thyroid dysfunction occurring during cytokine therapy is associated with improved tumor control and increased overall survival. Such predictive ability was reported in a large retrospective study of 1535 patients being treated with IL-2,[78] but other prospective trials did not find this correlation.[79] The most significant risk factors for the development of thyroid dysfunction are positive thyroid antibodies and female gender. Thyroid function testing should be completed before starting therapy, periodically throughout treatment, and a few months following treatment.[79]

IFN-α therapy has been linked to the development of thyroid dysfunction in reports, varying from 1% to 35%.[64] A series including 1233 patients with hepatitis C who were euthyroid before receiving IFN-α identified thyroid events in 16.7%, including approximately 5% with thyrotoxicosis and 12% with hypothyroidism.[80] LT4 supplementation should be used as required, and IFN-α therapy is not generally interrupted. Graves disease may also occur in patients treated with IFN-α,[81] but this is uncommon. In these cases, discontinuation of IFN-α therapy did not lead to remission of thyrotoxicosis,[81] though this approach has been recommended.[64] The presence of TPO antibodies prior to initiation of IFN-α therapy has a positive predictive value of 67% for the development of thyroid dysfunction.[65] Screening for thyroid antibodies before the start of therapy and continued monitoring during and after treatment are recommended. There have been conflicting reports regarding recovery of thyroid function following discontinuation of IFN-α therapy, with small series showing high rates of recovery and euthyroidism after biphasic thyroiditis.[82] Recurrent thyroiditis can also be seen with repeat courses of IFN-α therapy.[65]

TKIs are frequently associated with thyroid dysfunction due to destructive thyroiditis, likely resulting from vascular damage and ischemia. Thyroid dysfunction is highest with TKIs that target vascular endothelial growth factor receptors 1 to 3 and platelet-derived growth factor receptors. A thyrotoxic phase is seen after a median of 6 weeks, followed by hypothyroidism occurring after a median of 22 weeks, but the ranges of onset for both phases are quite broad.[50] The most widely-reported changes occur in patients receiving sunitinib for metastatic renal cell carcinoma or gastrointestinal stromal tumors.[83,84] Sunitinib is given in 6-week cycles, with chemotherapy being delivered over 4 weeks (ON phase) with 2 weeks off in between (OFF phase). An elevation in TSH is frequently seen during the ON phase that normalizes during the OFF phase but can become persistent after many cycles of therapy. In three large clinical trials involving patients with renal cell carcinoma, hypothyroidism occurred in 14% to 25%.[85-87] Most cases were rated as mild to moderate in severity, but rare patients experienced severe dysfunction. In a trial including 42 participants with normal thyroid function before receiving sunitinib, hypothyroidism occurred in 36%, many with TSH values greater than 20 mIU/L.[84] Forty percent of patients were found to have transient thyrotoxicosis prior to becoming hypothyroid, consistent with destructive thyroiditis. Hypothyroidism may be transient, but persistence after completion of therapy has been reported in up to 37.9% (range 10%–37.9%) of patients.[50] The likelihood that hypothyroidism will occur increases with longer duration of therapy. Overall, thyroid dysfunction with TKIs is treated either symptomatically or with thyroid hormone replacement, without having to discontinue therapy. Multiple surveillance algorithms have been suggested for surveillance of thyroid function depending on the type of TKI being used, but generally monthly testing is recommended during the treatment period.[50,88,89]

KEY POINTS: Tyrosine Kinase Inhibitors

- Tyrosine kinase inhibitor (TKI) therapy is frequently associated with thyroid dysfunction due to destructive thyroiditis.
- Thyroid dysfunction is treated either symptomatically or with thyroid hormone replacement without having to discontinue therapy.
- Monthly thyroid testing is recommended during the treatment period.

DRUGS AFFECTING PROTEIN BINDING OF THYROID HORMONE

Changes in Binding Proteins

More than 99% of T4 and T3 is bound to plasma proteins, including TBG, transthyretin, and albumin. TBG is a glycoprotein made in the liver and the primary transport protein for T4 and T3 molecules, accountable for approximately 70% of protein binding, with the remainder bound by transthyretin and albumin. As these binding proteins act as a natural reservoir, changes in their concentration can affect the balance of free and bound thyroid hormone.[90,91] While the normal thyroid gland accommodates changes in binding proteins with commensurate changes in thyroid hormone production, patients whose thyroid glands are compromised by diminished thyroid reserve or dependent on exogenous thyroid hormone therapy are unable to do so, resulting in hypothyroidism. Numerous medications affect plasma protein concentrations, and thus serum thyroid hormone concentrations.

Estrogen-containing preparations. Estrogen therapy is the most clinically significant cause of increased TBG. Estrogen increases the hepatic sialylation of TBG, resulting in decreased renal clearance rates and a subsequent dose-dependent rise in serum concentration.[92] These increases occur within 2 weeks of starting therapy, and a steady state is achieved within 4 to 8 weeks. Typical doses of ethinyl estradiol (20–35 μg per day) or conjugated estrogen (0.625 mg per day), increase TBG concentrations by 30% to 60%, resulting in increased circulating total T4 (TT4) by 20% to 35%. In patients taking LT4 for hypothyroidism, thyroid function should be monitored, and the dose increased or decreased as needed after starting or stopping estrogen therapy, respectively.[93] Because transdermal estrogen preparations evade first-pass hepatic effects seen with oral therapy, they do not raise TBG, and no LT4 dose adjustment is required with these agents.[94]

Selective estrogen receptor modifiers (SERMs) have estrogen-agonist effects in the liver, resulting in modest TBG elevations. Tamoxifen increases TBG by 24% to 30% in patients with normal thyroid function.[95,96] The SERMs raloxifene and droloxifene increase TBG to a lesser extent than tamoxifen, with no effects on free thyroid hormone levels.[97,98]

Opioids. Studies of heroin and methadone users found an increase in TBG by up to 50%, with corresponding increases in TT4 and TT3 levels.[99,100] The etiology is thought to relate to changes in production at the hepatic level, possibly aggravated by increased estrogen or decreased androgen. There are insufficient data to determine whether patients taking LT4 for hypothyroidism require LT4 dose adjustments when starting opioid medications.[100]

Mitotane, in addition to causing central and primary hypothyroidism, has been shown to increase TBG through unknown mechanisms, thereby increasing TT4 and TT3.[31]

5-Fluorouracil (5-FU) is used in the treatment of several solid malignancies and associated with increases in TT4 and TT3 levels. As patients remain euthyroid with normal TSH and FT4 levels, an effect on thyroid hormone binding proteins is likely. No treatment is necessary, and long-term therapy with 5-FU has not been shown to significantly impair thyroid function.[101]

Androgen therapy results in a decreased concentration of TBG in the serum, with subsequent reduction in of TT4 and TT3, which occur within 2 weeks of starting therapy. A steady state is achieved within 4 to 8 weeks for TBG and 8 to 12 weeks for T4. In patients with normal thyroid function, TSH concentrations decrease slightly, but patients remain euthyroid. In a small group of breast cancer patients with known hypothyroidism on thyroid replacement therapy, the addition of the androgen fluoxymesterone led to increases of FT4, reductions in TSH, and symptoms of thyroid hormone excess, necessitating LT4 dose reduction by 25% to 50%.[102] Changes were reversible with the discontinuation of therapy, and TBG levels returned to baseline within 8 to 10 weeks of discontinuing therapy.[102] A study of transgender males on testosterone therapy revealed a 26% decrease in TT4 and a 14% decrease in TBG after 4 months of testosterone therapy.[103] In studies using nonaromatizable androgens, a greater than 50% decrease in TBG has been observed.[91] It is unknown if this decline is related to reduced synthesis or enhanced clearance of TBG. It is important for clinicians to be aware of these effects in patients receiving thyroid hormone therapy. Monitoring of thyroid function should be done within 6 to 8 weeks after starting androgen therapy in patients with known thyroid disease.[91]

Danazol is a synthetic steroid with antigonadotropic, anabolic, and mildly androgenic properties used mainly in the treatment of endometriosis. It has been shown to decrease T4 but not affect TSH. These effects are thought to be due to decreased TBG resulting from the its androgenic properties.[104]

Glucocorticoids also affect the concentration of thyroid hormone–binding proteins, specifically by decreasing TBG and increasing T4-binding prealbumin.[105,106] Increased TBG was seen irrespective of the mode of administration but was more pronounced in the group treated with oral rather than with IV glucocorticoids.[105]

Niacin (nicotinic acid, B3), at doses of 0.5 to 4.0 g daily to treat hyperlipidemia caused a 23% decrease in serum TBG concentration with a subsequent decrease in serum TT4 by 21% and TT3 by 13% in five patients, after 0.5 to 3.5 years of therapy.[107] FT4 and TSH concentrations remained unchanged. These effects are most prominent with doses greater than 2 g daily and are reversible with discontinuation of the medication.

Displacement of Thyroid Hormone From Binding Proteins

Antiepileptics (phenytoin, carbamazepine). Phenytoin and carbamazepine have been shown to displace T4 and T3 from binding proteins when measured using an ultrafiltration assay in undiluted serum.[108] This displacement results in transient increases in free thyroid hormones and a compensatory decrease in TSH, followed by a decrease in TT4, and a new steady state with lower TT4 but normal levels of FT4 (see also the later section: Drugs Causing Abnormal Thyroid Testing in Euthyroid Patients) and TSH.

Nonsteroidal anti-inflammatory drugs, specifically salsalate and acetylsalicylic acid (aspirin), compete with thyroid hormone binding to predominantly TBG, and to a lesser extent transthyretin and albumin.[109] This results in decreased concentrations of TT4 and TT3 with a transient increase in their free fractions. A transient decrease in TSH ensues before a new equilibrium is reached. Salsalate in doses of greater than 1.5g/day can decrease TT4 by nearly 40%.[109]

Furosemide, a potent loop diuretic, has no effect on thyroid function at usual doses. However, a single large dose can compete with T4 for binding sites on TBG, prealbumin, and albumin.[110] These effects were also noted in critically ill patients with acute renal failure who received large cumulative doses of furosemide.[111] A pronounced decrease in TT4 occurs, which persists while serum concentrations of the drug remain elevated. When compared with other drugs that compete for T4 binding sites (fenclofenac, mefenamic acid, and sodium salicylate), furosemide was the most potent.[110] Effects are dose-dependent, starting at an oral dose of 80 mg or higher.[112] The length of time from drug administration, rate of renal clearance, and serum concentrations of albumin also affect the magnitude of the effect.

DRUGS AFFECTING THYROID HORMONE ACTIVATION, METABOLISM, AND EXCRETION

Thyroxine-to-Triiodothyronine Conversion

Amiodarone inhibits both peripheral and central monodeiodination of T4-to-T3 by D1 and D2, respectively. The manifestations of these effects in euthyroid persons prescribed amiodarone will be discussed later in the chapter.

Propranolol therapy at daily doses of 160 mg or higher leads to elevations in T4 levels, suggesting impaired conversion to T3, in clinically euthyroid persons.[113] Even a single propranolol dose of 40 mg in euthyroid participants was found to lead to modest reductions in T3 levels within the normal range.[114] In one study, hyperthyroid patients treated only with propranolol, alprenolol, atenolol, or metoprolol had reductions in T3 levels of 8% to 20%, which may have therapeutic importance in patients being treated for severe thyrotoxicosis or thyroid storm.[115]

Glucocorticoids inhibit outer ring deiodination, leading to a decreased conversion of T4-to-T3 with reciprocal increase in reverse T3 (rT3). They also result in decreased iodine uptake into the thyroid gland, manifested by increased urinary excretion of iodine.[105] Decreases in serum T3 levels reach a nadir at 30 hours. This effect may last for several days, and is more pronounced when using glucocorticoids with long biological half-lives, such as dexamethasone.[116,117]

Thyroid Hormone Metabolism

Antiepileptic drugs including phenobarbital, phenytoin, and carbamazepine are considered enzyme-inducing, as manifested by their ability to stimulate hepatic cytochrome P-450 enzymes and consequently increase the metabolism of thyroid hormone through glucuronidation and sulfation conjugation pathways.[76] In patients taking thyroid hormone for hypothyroidism, a dose increase may be needed when these antiepileptic drugs are added. These effects are reversible when these drugs are discontinued.[118,119] Oxcarbazepine has less enzyme induction activity compared with carbamazepine, but similar effects can be seen at higher doses.[120] Newer antiepileptics, including lamotrigine, levetriacetam, tiagabine, and vigabatrin, have not consistently been shown to alter thyroid function.[120]

Rifampin, an antibiotic used mostly in the treatment of tuberculosis, also stimulates hepatic thyroid hormone metabolism pathways, as occurs with the antiepileptic drugs noted above. T4 concentrations decrease, with a compensatory increase in TSH. This is important clinically for patients receiving LT4 therapy, who may require dose adjustment. In one study, after initiation of rifampin, an increase in LT4 was needed in 50% of patients on TSH suppressive therapy for thyroid cancer and 26% of patients on replacement therapy.[121] In individuals without baseline thyroid dysfunction, rifampin reduces thyroid hormone levels without significantly elevating TSH levels. Rifampin-related changes in thyroid function resolve after cessation of treatment.[122]

TKIs. In addition to damage to the thyroid, an increased LT4 dose requirement has been observed in athyreotic patients being treated with imatinib, motesanib, sorafenib, sunitinib, and vandetanib.[76] Hypothyroid patients receiving imatinib in one study required average LT4 dose increases of 47%.[123] Increased thyroid hormone metabolism through activation of type 3 deiodinase[124] and inhibitory effects on MCT8-mediated thyroid hormone transport,[125] as well as other mechanisms,[50] have been implicated as potential contributors to this finding.

Bexarotene, as noted above, enhances the peripheral metabolism of thyroid hormone. One study showed parallel decreases in serum T4, T3, and rT3 levels and an increase in the T3/rT3 ratio, suggesting increased metabolism through nondeiodinase pathways.[28]

Disposal of Thyroid Hormone

Bile acid sequestrants (cholestyramine, colestipol, colesevelam) enhance thyroid hormone elimination primarily through interference with enterohepatic circulation. Because of these effects, bile acid sequestrants have been useful in the treatment of both endogenous and exogenous causes of thyrotoxicosis.[126,127] Patients on LT4 replacement therapy who are started on a bile acid sequestrant require monitoring of thyroid function tests, with LT4 dose changes possibly required. Thyroid function is not affected by bile acid sequestrants in persons with normal thyroids.

DRUGS AFFECTING THE ABSORPTION OF THYROID HORMONE PREPARATIONS

LT4 absorption is pH-dependent, and 60% to 80% of an oral dose is absorbed over the first 3 hours after ingestion. Anything taken by mouth, including drugs or food, can significantly reduce the bioavailability of LT4. The extent of this effect is dependent on the timing of LT4 dosing relative to intake of food or medications that impair absorption. Multiple over-the-counter, as well as prescribed, medications impair the absorption of LT4, as has been recently reviewed.[128] Patients should be advised to separate LT4 from these medications by at least 4 hours to avoid potential interaction.

Iron preparations, when taken simultaneously with LT4, have been shown to cause a variable reduction in T4 absorption. In a study of 14 previously well-controlled patients on LT4 initiated on 300 mg ferrous sulfate and advised to take the two medications simultaneously, TSH concentrations increased from a mean of 2.8 mIU/L to 5.4 mIU/L after 12 weeks, with an increase in hypothyroid symptoms but no effect on FT4 index.[129] Although no specific study has examined the optimal separation time between these medications, at least 4 hours' separation is generally advised.

Calcium salts are frequently used over-the-counter medications. Calcium carbonate is known to decrease absorption of LT4, but this may also occur with other calcium preparations. A study of healthy subjects given 1000 mcg of LT4 alone or in combination with one of the three calcium salts (carbonate, citrate, or acetate) found a 20% to 25% reduction in LT4 absorption with each of these preparations.[130]

Aluminum hydroxide is used mostly as an antacid and decreases LT4 absorption through drug–drug complexing. A study of five hypothyroid patients taking stable doses of LT4 before and 2 weeks after starting aluminum hydroxide containing antacids found that mean TSH levels increased from 2.6 mIU/L to 7.2 mIU/L, despite instructing participants to separate the two drugs by at least 2 hours.[131]

Bile acid sequestrants, in addition to interference with enterohepatic recycling of thyroid hormone, physically bind to LT4, resulting in decreased intestinal absorption. Colesevelam 3.75 g, given concurrently with an absorption test dose of 600 mcg LT4, nearly completely obliterated the expected increase in serum concentration of T4 unless LT4 was given 4 hours before giving the colesevelam.[132] Cholestyramine given to normal subjects at intervals from 1 to 5 hours before a tracer dose of radiolabeled LT4 showed significant increases in fecal radioactivity that decreased after a 5-hour separation between the two drugs, suggesting impaired absorption of the radiolabeled drug, although decreased enterohepatic recycling may also have contributed to this finding.[133]

Sucralfate, commonly used in the treatment of duodenal ulcers, has been inconsistently linked to impaired absorption LT4. *In vitro* conditions show strong binding of sucralfate to LT4, which is a proposed mechanism for decreased absorption when these two medications are taken concurrently. One study performing a LT4 absorption test in which 1000 mcg was administered to healthy volunteers found only 23% absorption of LT4 when taken concurrently with 1 g sucralfate, compared with 80% absorption when taken alone.[134] Conversely, a study of 10 patients taking stable doses of LT4 found no significant change in T4 or TSH values after adding in sucralfate 1 g, taken concurrently with LT4 for 6 weeks.[135] Despite the conflicting results, patients taking LT4 and sucralfate should separate the medications by more than 4 hours, and thyroid function tests should be monitored.

Raloxifene has been suggested in case reports to decrease absorption of LT4 when the two are taken concurrently, manifested by a rise in TSH after raloxifene was started. In one such report abnormal results were obtained on a LT4 absorption test, despite the separation of raloxifene from the LT4 by several hours.[136]

Proton pump inhibitors (PPIs) are believed to reduce LT4 absorption by decreasing gastric acidity. Some reports show an increase in TSH after starting PPIs, necessitating an LT4 dose

Low thyrotropin signal antibody detected, yielding falsely low thyrotropin level

Fig. 84.3 **Biotin interference in two-site (sandwich) thyrotropin assay.** Biotin, when taken in excess, can result in variable interference in assays, such as that for thyrotropin, that utilize biotinylated reagents. Two-site assays include two antibodies: an antithyrotropin antibody containing a signal moiety (site 1) and a biotinylated antithyrotropin antibody (site 2). Streptavidin is fixed to a solid phase such as an enzyme-linked immunosorbent assay and will bind these antibodies forming a complex (**A**). Normally, the complex of thyrotropin bound to the two antithyrotropin antibodies binds to streptavidin. After washing (**B**), the signal is directly proportional to the thyrotropin concentration in the specimen. However, if excess biotin is present, the complex cannot compete effectively for streptavidin binding on the solid phase (**C**), and after washing, a low signal results in a falsely low thyrotropin level (**D**).

increase of approximately 35%,[137] while other studies found no change in TSH after PPI initiation.[138,139] Despite the conflicting results, it is generally recommended that thyroid function tests are monitored after initiation of PPI therapy. Clinicians may also consider liquid LT4 in patients affected by LT4 malabsorption for whom an acidic gastric environment required for tablet dissolution cannot be maintained.[128,137]

DRUGS CAUSING ABNORMAL THYROID TESTING IN EUTHYROID PATIENTS

Biotin, vitamin B7, is prescribed for MS and several rare metabolic disorders but is commonly used as an over-the-counter supplement for hair, skin, and nail enhancement. It is also found in combined B-complex supplements. Biotinylation is utilized in many two-site and competitive immunoassays due to the strong interaction of biotin with streptavidin. In most current TSH assays, two antithyrotropin antibodies (one biotinylated and the other with a signal moiety attached) are used to bind or "sandwich" thyrotropin, forming an antigen–antibody–antigen complex. This complex then binds to the affixed streptavidin and is measured, with signal being directly proportional to the TSH concentration (Fig. 84.3). Excess serum biotin can displace the biotinylated antibody-antigen-antibody complex from streptavidin, resulting in falsely low TSH reading.[1] Conversely, in competitive assays used to measure FT4 and FT3, the signal is inversely proportional to hormone concentrations, and excess biotin in the patient's serum can lead to an overestimation of FT4 and FT3.[1] This is caused by binding of free biotin to the streptavidin sites, thereby blocking the biotinylated antibody and analyte of interest. With nowhere to bind, this complex is washed away, causing a decreased signal, resulting in a falsely increased estimation of FT4 or FT3 (Fig. 84.4).[1,140] Together, falsely high thyroid hormone measurements and falsely low TSH results are easily confused with overt thyrotoxicosis. While intake of 35 to 70 mcg daily does not interfere with these assays, higher doses of 1.5 to 300 mg/day cause significant interference with some, but not all, assays utilizing biotinylation.[141] Patients taking biotin should stop

D
Excess biotin occupies streptavidin binding sites
Low signal detected, yielding falsely elevated free T_4 level

Fig. 84.4 Biotin interference in competitive free thyroxine (T4) immunoassay. Biotin, when taken in excess, can result in variable interference in competitive immunoassays (which includes free T4, free triiodothyronine, and thyrotropin receptor antibodies). Free T4 assay components include labeled T4, a biotinylated anti-T4 antibody, and a streptavidin bound to a solid phase (**A**). Normally, free T4 in serum competes with labeled T4 for binding to the biotinylated anti-T4 antibody. After washing, the amount of signal is inversely proportional to the serum free T4 level (**B**). If excess biotin is present, these molecules occupy the streptavidin binding sites, preventing the anti-T4 antibody from binding (**C**). After washing, a low or absent signal leads to calculation of a falsely elevated free T4 value (**D**).

this supplement for several days before drawing laboratory testing for thyroid function.

KEY POINTS: Biotin

- Biotin has no direct effect on thyroid function but does interfere with biotinylated lab assay resulting in abnormal thyroid test results. The following can be seen based on the type of assay used:
- Two-site ("sandwich") assay ê falsely low TSH reading
- Competitive immunoassay ê falsely high free thyroxine (FT4) and free triiodothyronine (FT3)
- Patients should be advised to stop biotin for several days prior to laboratory testing for thyroid function.

Amiodarone. In addition to causing true hypothyroidism and thyrotoxicosis, amiodarone leads to expected changes in thyroid testing results in euthyroid persons.[1,42,44] Inhibition of peripheral and central T4-to-T3 conversion by amiodarone and its major active metabolite, desethylamiodarone, leads to reductions in circulating and intrapituitary T3 levels, thereby stimulating thyrotropin release through an absence of negative feedback. Increases in thyrotropin prompt thyroidal release of T4, which accumulates further because of inhibited conversion to T3. The net effect of these changes is a serum TSH level that is elevated or at the high end of the normal range, high levels of TT4 and FT4, and a T3 level at the low end of the normal range in a euthyroid patient. A steady state is usually achieved within 3 months with normalization or near-normalization of TSH, but thyroid hormone levels remain elevated.

Phenytoin and **carbamazepine**, as noted earlier, displace thyroid hormone from binding proteins. Patients on chronic therapy with these agents will have lower TT4 and TT3 levels, while maintaining normal TSH values. Free thyroid hormones measured by equilibrium dialysis are also normal. However, in assays that use serial dilution, free thyroid hormone concentrations are underestimated, appearing falsely low, suggesting central hypothyroidism. As a result, clinicians depending on FT4 measurements utilizing serum dilution should base treatment decisions on TSH values or utilize FT4 assays that do not require serum dilution.[108]

Salsalate, by displacing thyroid hormone from binding proteins, reduces TT4 and TT3 levels. Patients on chronic therapy with salsalate will have low total thyroid hormones and a normal TSH, which, as is the case with dilantin and carbamazepine, can be mistaken for central hypothyroidism.[142]

Heparin liberates lipoprotein lipase from the vascular endothelium. Blood samples from a patient receiving heparin have increased lipoprotein lipase activity, which persists *in vitro*. Free thyroid hormone assays with lengthy incubation periods, such as equilibrium dialysis, are most affected, because free fatty acids released by the lipase have longer times to displace T4 and T3 from binding proteins, causing spuriously high values.[143] Similar effects are seen with low molecular weight heparin preparations.[144] Standard competitive free hormone assays and thyrotropin testing are generally unaffected, so the testing can be repeated with the use of these assays. Alternatively, if thyroid dysfunction is a concern, clinicians can draw thyroid before staring heparin therapy or prior to the next heparin dose, or at a minimum 10 hours after injection to avoid these spurious results and unnecessary evaluation.[144,145]

THE EFFECT OF THYROID DYSFUNCTION ON DRUG METABOLISM

Throughout this chapter, we have discussed how different drugs affect thyroid function. Here we will review what is known about the impact of thyroid dysfunction on drug metabolism.

Warfarin, a vitamin K antagonist, is a commonly used anticoagulant. Hyperthyroidism increases the catabolism of vitamin K–dependent clotting factors, prolonging the prothrombin time. Therefore, the warfarin dose commonly needs to be decreased in patients who develop hyperthyroidism while taking this drug, which may seem counterintuitive. The half-life of warfarin is not affected by hyperthyroidism.[146,147]

Digoxin, a cardiac glycoside used for the treatment of atrial fibrillation may require dose adjustments in patients with thyroid dysfunction. Higher doses are often required in thyrotoxic patients, while lower doses are needed in patients with severe hypothyroidism. These effects are thought to be due to enhanced (hyperthyroidism) or delayed (hypothyroidism) clearance of the medication through the renal and biliary systems.[146] Increased cardiac excitability in hyperthyroidism, combined with increased digoxin clearance, may contribute to an increased risk of recurrent atrial fibrillation in a newly thyrotoxic patient previously well-controlled on digoxin therapy.

Acetaminophen demonstrates a more rapid absorption, earlier peaking, and more rapid decrease in patients with untreated thyrotoxicosis, indicating a balance between increased absorption and more rapid metabolism.[148]

Propranolol undergoes a significant hepatic first-pass metabolism, which is accelerated in thyrotoxicosis and reduced in hypothyroidism.[149,150] In addition, increased hepatic blood flow in thyrotoxicosis contributes to a shorter half-life and lower serum steady-state concentrations, while hypothyroidism has the opposite effect. Clinically, this is manifested by higher propranolol dose requirements in thyrotoxic patients compared to those who are euthyroid or hypothyroid.

Glucocorticoids are metabolized by hepatic oxidases, which may be functionally affected by changes in thyroid functional status. Hepatic clearance is delayed in hypothyroidism, resulting in an increased half-life and decreased urinary cortisol metabolite concentrations. Conversely, a decreased glucocorticoid half-life is observed in thyrotoxicosis.[151] These findings are clinically relevant, as increased metabolism of corticosteroids during thyrotoxicosis could precipitate adrenal crisis in a patient dependent on adrenal replacement therapy or in patients with borderline adrenal function at baseline.[152,153]

Statin medication usage has been extensively linked to myalgias, myositis, and rhabdomyolysis, and the risk of these adverse effects is increased with hypothyroidism.[154] The mechanism of this association is unknown but may relate to higher serum statin levels during hypothyroidism.[155] Clinically, ensuring a patient is euthyroid prior to starting or increasing a statin dose is important, because correcting hypothyroidism may both improve the dyslipidemia and decrease the risk of statin-related myopathic effects.

SUMMARY AND FUTURE DIRECTIONS

Drugs may disturb control of the thyroid at the hypothalamic-pituitary level, cause thyroid destruction either directly or through the immune system, initiate or aggravate existing thyroid autoimmunity, and cause hyperthyroidism, hypothyroidism, or both. Drugs affect binding of thyroid hormone to protein carriers and the activation of T4-to-T3, as well as the metabolism, recycling, and elimination of thyroid hormone. Many drugs affect the efficiency of exogenous thyroid hormone therapy, requiring vigilance to prevent both undertreatment while taking them and overtreatment after stopping. Equally concerning, drugs may alter thyroid laboratory results in a manner that artifactually mimics primary hyperthyroidism, central hypothyroidism, and central hyperthyroidism despite the maintenance of a euthyroid state. Being aware of these interactions allows clinicians to monitor for them, intervene when necessary, and avoid needless testing or inappropriate treatment. Each drug, whether newly released or an established mainstay of therapy, should be considered for its potential to interact with the thyroid.

INTRODUCTION AND HISTORICAL BACKGROUND

The adrenal gland is an essential endocrine organ that functions to produce and secrete steroid and catecholamine hormones. Bartholomeus Eustachius (1520–1574) published the first detailed illustrations of the adrenal as a discrete organ in 1563 and proposed that the gland likely had an important, yet unknown, function.[1] This notion was highly controversial, with many prominent anatomists and physicians at the time arguing that Eustachius had simply observed part of the kidney.[2] Despite its ambiguity, the adrenal gland remained the subject of in-depth study. Cuvier (1769–1832) was the first to recognize the heterogeneous nature of the gland, with an outer portion that is morphologically distinct from the inner. These separate regions were respectively termed the "*cortex*" and "*medulla*" by N. Nagel in 1836.[3] With advancements in compound microscopy techniques, R.A. von Kölliker (1817–1905) provided a detailed microscopic analysis in 1852 and concluded, "the cortical and medullary substances are physiologically distinct and have different functions."[4,5]

Throughout these observational advances, there was widespread conjecture regarding the actual function of the adrenal gland. It was not until 1855, with the work of Thomas Addison, that the adrenal was associated with human disease. Addison was investigating an unusual form of anemia and observed a similar set of symptoms in a series of 11 patients, each of whom had gross destruction of both adrenal glands upon autopsy. In his work "*On the Constitutional and Local Effects of Disease of the Suprarenal Capsule,*" Addison reported the first case series of adrenal insufficiency.[6] This disease, later recognized as Addison's disease, most often results from autoimmune destruction of the glands.[7] In 1856, Charles Brown-Sequard confirmed the vital importance of the adrenal gland by demonstrating that guinea pigs were unable to survive bilateral adrenalectomy.[8] In the twentieth century, the actual substances produced by the adrenal glands were identified. John Jacob Abel and Jōkichi Takamine independently isolated epinephrine, or adrenaline, as the first principle hormone from the adrenal medulla.[9] Edward Calvin Kendall, Tadeus Reichstein, and Philip Showalter Hench later collectively elucidated the structure and biological effects of steroid hormones produced by the adrenal cortex, for which they shared the 1950 Nobel Prize in Physiology or Medicine.[10] Since these seminal advances in the field, the adrenal gland has been shown to play an important role in a wide range of physiological processes throughout the body. Further, adrenal gland dysfunction leads to human diseases with severe morbidity. This chapter will focus on the development and homeostatic maintenance of the gland, which is fundamental to understanding and managing adrenal diseases.

KEY POINTS

- The vital importance of the adrenal gland was not recognized until 1855, when Thomas Addison described the first case series of adrenal insufficiency.
- The adrenal gland is an essential endocrine organ that functions to produce steroid and catecholamine hormones.

ADRENAL STRUCTURE AND FUNCTION

Anatomy

The adrenal glands, which are also known as the suprarenal glands, are located above the upper pole of each kidney. Although both glands function similarly to produce and secrete hormones, the pair displays an asymmetry with respect to size and shape. The right adrenal gland is pyramid-shaped and smaller compared with the left, which is crescent-shaped. Each adult human adrenal gland measures approximately 3 cm in width and 5 cm in length and weighs 4 to 5 grams.[11] Notably, the adrenal is comprised of two distinct endocrine organs, the outer cortex and centrally located medulla, which each have a unique embryonic origin and function. An outermost mesenchymal capsule encases the entire gland (Fig. 85.1).

Adrenal Cortex

The adrenal cortex is derived from intermediate mesoderm and functions to produce steroid hormones. Specifically, the adrenal cortex is responsible for the production and secretion of mineralocorticoids, glucocorticoids, and androgens. Each of these steroids is synthesized from the common precursor cholesterol but is produced in response to a different physiological demand. To enable this type of rapid and precise response to varying organismal needs, the cortex is organized into three concentric regions or "zones" that are functionally specialized. Julius Arnold first described the three subdivisions within the adrenal cortex in 1866. Based entirely on histological observations, Arnold named these the glomerulosa, fasciculata, and reticularis.[12] The nomenclature established by Arnold reflected the unique organization of cells within each zone, but it later became clear that function follows form, with each zone responsible for the production and secretion of specific hormones (Fig. 85.2). This functional specificity within each region is conferred by the expression of a different set of cytochrome P450 steroidogenic enzymes.[13]

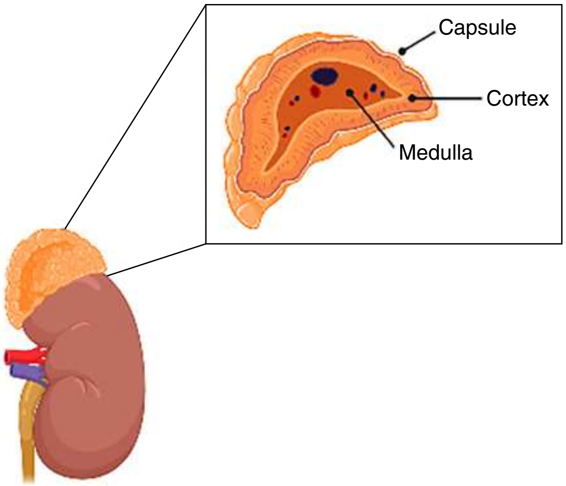

Fig. 85.1 **Adrenal gland structure.** The adrenal gland is located above the upper pole of each kidney. The centrally located medulla (catecholamine-producing) is surrounded by the adrenal cortex (steroid hormone-producing), and an outermost mesenchymal capsule encases the entire gland. Figure was created using BioRender (https://biorender.com/).

Zona Glomerulosa. The zona glomerulosa (zG) is located directly beneath the capsule and makes up approximately 15% of the cortex. The zG is comprised of cells that are organized into round clusters or functional units called glomeruli (Latin *glomus*, ball), which act to produce mineralocorticoids. Aldosterone is the primary mineralocorticoid and is regulated by angiotensin II (Ang II) as part of the renin-angiotensin-aldosterone system (RAAS). Aldosterone plays a central role in controlling blood pressure by regulating sodium balance and thereby influencing water retention and intravascular volume.[14]

Cells within the glomerulosa are interconnected and encased within a laminin B1-rich basal membrane.[15] During postnatal development, zG cells organize into multicellular rosettes of 10 to 15 cells that are connected at a single central point by adherens junction-mediated membrane constriction.[15] Morphogenesis into these mature rosette structures helps facilitate aldosterone production by coordinating the calcium-dependent signaling response following Ang II stimulation.[16] Notably, rosettes contain both CYP11B2-positive cells as well as CYP11B2-negative cells. CYP11B2 (or aldosterone synthase) catalyzes the conversion of deoxycorticosterone (DOC) into aldosterone, which is the final step in the synthesis of aldosterone from cholesterol. Thus, CYP11B2 marks those cells with the capacity to produce aldosterone,

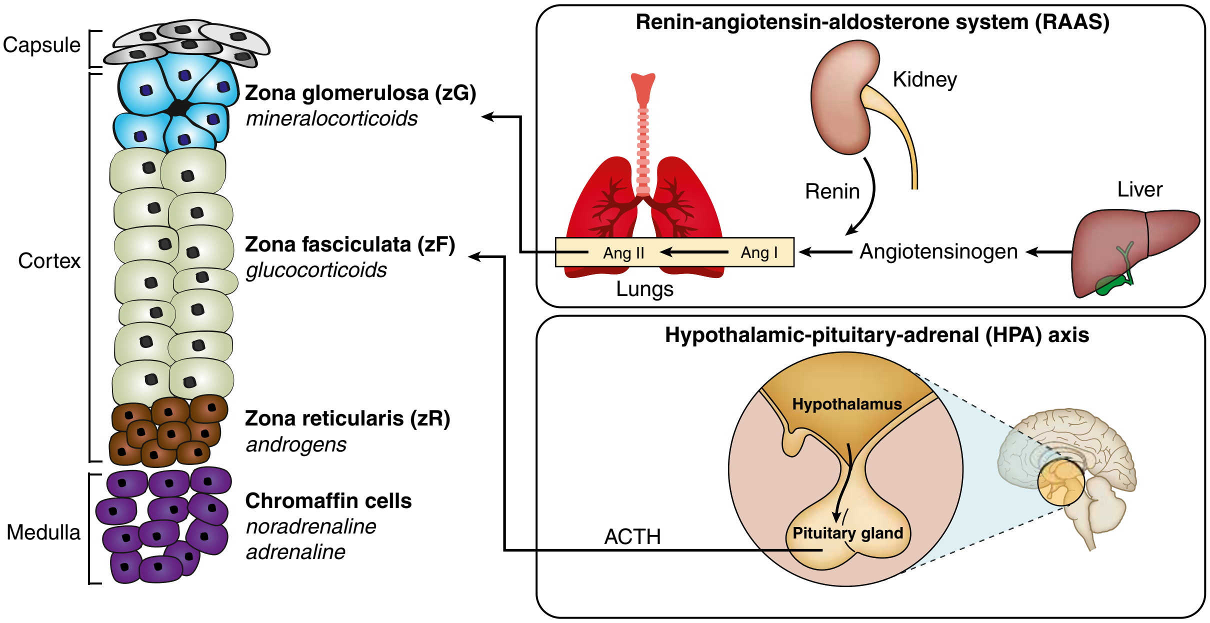

Fig. 85.2 **Adrenal gland function.** The inner medulla contains chromaffin cells that produce catecholamine hormones (noradrenaline and adrenaline). The outer cortex is subdivided into three functionally distinct zones. The zona glomerulosa (zG) is located just beneath the capsule and is composed of cells organized into round glomeruli. The zG functions to produce mineralocorticoids (aldosterone) in response to angiotensin II (Ang II) as part of the renin-angiotensin-aldosterone system (RAAS). The intermediate zona fasciculata (zF) contains cells organized into radial cords or fascicles. The zF functions to produce glucocorticoids (cortisol) in response to ACTH as part of the hypothalamic–pituitary–adrenal (HPA) axis. Finally, the innermost zona reticularis (zR) contains cells spread across a net-like structure and functions to produce androgens (DHEA and DHEA-S). Figure was created using BioRender (https://biorender.com/).

Fig. 85.3 **Adrenal gland structure across different species.** The structure of the adrenal gland, and particularly the adrenal cortex, is highly conserved between species. However, there are some key differences in mice and rats as compared with humans. The majority of mouse species *(middle)* do not express CYP17A1 after fetal development. Consequently, these animals synthesize corticosterone rather than cortisol as the main glucocorticoid, and they do not make adrenal androgens (i.e., they lack a functional zona reticularis). The mouse adrenal cortex contains an additional zone called the X zone, which is hypothesized to function in progesterone catabolism. The X zone is derived from the fetal cortex and regresses in males during puberty and in females after pregnancy. The rat adrenal cortex *(right)* contains a unique region between the zona glomerulosa (zG) and zone fasciculata (zF) called the undifferentiated zone (zU). This region is defined by a lack of expression of zG or zF differentiation markers and is proposed to contain progenitor cells that repopulate the cortex.

while CYP11B2-negative cells in the zG constitute a reservoir of cortical progenitor cells.[17]

Zona Fasciculata. Directly adjacent to the zG, the zona fasciculata (zF) is composed of cells organized into radial cords (Latin *fascicle*, bundle) that function to produce glucocorticoids. Cortisol is the main glucocorticoid in humans and is produced in response to adrenocorticotropin hormone (ACTH) as part of the hypothalamic–pituitary–adrenal axis. Cortisol has a wide range of effects throughout the body, including increased blood sugar through stimulation of gluconeogenesis and suppression of the immune system.[18]

Cells within the zF are characteristically polygonal and lipid-rich, with fenestrated capillaries encasing each cord to facilitate rapid hormone circulation. The production of glucocorticoids is driven by pituitary ACTH, which acts through the MC2R receptor in complex with the accessory protein MRAP.[19] The ultimate production of cortisol depends largely on two key enzymes, CYP17A1 and CYP11B1. CYP17A1 hydroxylase activity converts pregnenolone into 17α-OH-pregnenolone, which is then converted into 17α-OH-progesterone by 3βHSD. This is then converted to 11-deoxycortisol by CYP21 and into cortisol by CYP11B1. However, the majority of rodent species do not express *Cyp17a1* in the adrenal cortex after fetal development.[20] As a result, CYP11B1 instead converts DOC into corticosterone, which acts as the main glucocorticoid in these animals.

Zona Reticularis. The innermost zona reticularis (zR) contains cells spread across a mesh or net-like structure (Latin *rete*, net), which function to produce androgens. These include dehydroepiandrosterone (DHEA) and DHEA-sulfate (DHEA-S). DHEA is a weak androgen and estrogen receptor agonist itself but can be converted peripherally into more potent steroids, including testosterone and estradiol, and to a lesser extent, glucocorticoids.[21]

The zR is composed of polyhedral cells and first becomes morphologically distinguishable at 3 years of age in humans. It forms a continuous layer of cells by 6 years, when adrenal androgens synthesis significantly increases with the onset of adrenarche, and further enlarges until 13 years of age.[21,22] The production of DHEA is mediated in large part by CYP17A1. As a result, rodents deficient for adrenal *Cyp17a1* lack a functional zR and do not produce adrenal androgens. While CYP17A1 is expressed in both the zF and zR, lower expression of 3βHSD in the zR and high expression of cytochrome B5 (CYB5) and P450 oxydoreductase (POR) favors CYP17A1 lyase activity, thus rerouting 17α-OH-pregnenolone into DHEA synthesis. zR specific expression of SULT2A1 further allows production of DHEA-S.[21]

Mouse X Zone and Rat Undifferentiated Zone. Mice and rats each contain an additional cortical region not found in the human adrenal gland (Fig. 85.3). The mouse adrenal cortex contains a transient inner zone called the "X zone" that is located at the cortical-medullary boundary.[23] The origin of the X zone was debated for decades, but lineage-tracing studies have now demonstrated that this region is a remnant of fetal cortex.[24] The X zone is initially quite narrow just after birth and becomes most evident by 3 weeks of age before ultimately regressing in males after puberty and in females during pregnancy.[23] The X zone is distinguished based on the expression of specific molecular markers, including 20-α-hydroxysteroid dehydrogenase (20αHSD)[25] and phosphatidylinositol-4-phosphate 3-kinase c2 domain-containing gamma polypeptide (PIK3C2G)[26]. The function of the X zone remains poorly understood, though it has been hypothesized to participate in progesterone catabolism because 20αHSD catalyzes the reduction of progesterone and deoxycorticosterone into their 20α-hydroxylated derivatives.[25] However, the role of this enzymatic activity in the adrenal cortex of rodents remains unclear, as 20αHSD knockout adrenals are not distinguishable from their wild-type counterparts.[25]

The rat adrenal cortex contains a unique region between the zG and zF known as the "undifferentiated zone" (zU).[27] The zU is defined by a lack of zG or zF differentiation markers and contains undifferentiated progenitor cells that may help replenish the adrenal cortex.[28] In mice, stem and progenitor cells are contained within the outer mesenchymal capsule and underlying zG, respectively.[17,29,30]

Adrenal Medulla. The adrenal medulla is derived from ectodermal neural crest cells and functions to produce catecholamines.[31] Unlike steroid hormones produced by the adrenal cortex, catecholamines are derived from the amino acid tyrosine and are water-soluble. Tyrosine is converted through a multistep process into dopamine followed by the predominant catecholamines, noradrenaline, and adrenaline (also called norepinephrine and epinephrine, respectively). Catecholamines are produced in chromaffin cells that are grouped around venous sinusoids, which facilitate their rapid circulation during the "fight-or-flight" response. The release of catecholamines is directly controlled by preganglionic nerve fibers that provide a neural stimulus and connect chromaffin cells to the sympathetic division of the autonomic nervous system. Adrenaline acts as a hormone to enhance cardiac output through increased heart rate and blood pressure, and to increase glucose metabolism in the liver and muscle tissue. Noradrenaline is released in smaller amounts and acts as a neurotransmitter to promote vasoconstriction, thus increasing blood pressure.

Vasculature. To facilitate the rapid delivery of hormones into the bloodstream, the adrenal gland contains a rich vascular network. Blood is supplied from three main arteries: the superior, middle, and inferior adrenal artery, which derive from the inferior phrenic artery, the abdominal aorta, and the renal artery, respectively.[32] These major vessels form a plexus, or branched network of arteries, in the capsule, which then descend centripetally through the cortical layers. In the medulla, arteries form a capillary network that directs blood flow into the medullary vein before ultimately draining into either the inferior vena cava on the right side or the left renal vein. This extensive vascular network ensures that most cells are in close proximity (1–2 cells) to vascular endothelial cells, thus facilitating rapid hormone distribution throughout the body.

Nerve Supply. In contrast to the cortex, where steroid production is controlled in large part by hormonal stimulation, catecholamine production from the medulla is regulated by synaptic stimulation. The medulla is innervated by preganglionic nerve fibers of the sympathetic nervous system that originate in the intermediolateral cell column of the spinal cord.[33] These fibers form the greater splanchnic nerve, from which some fibers directly enter the adrenal gland to synapse at the membrane of chromaffin cells. Other fibers from the greater splanchnic nerve synapse at the celiac ganglion, whose postsynaptic fibers innervate blood vessels in the adrenal gland. Together, this network of nerve fibers enables the medulla to release its neurohormones in response to activation of the sympathetic nervous system.

KEY POINTS

- The adrenal gland is composed of two distinct endocrine organs: the inner medulla derived from ectodermal neural crest cells that produces catecholamine hormones, and the outer cortex derived from intermediate mesoderm that produces steroid hormones.
- The cortex is subdivided into three structurally and functionally distinct zones: the outer zona glomerulosa produces mineralocorticoids in response to angiotensin II as part of the renin-angiotensin-aldosterone system, the intermediate zona fasciculata produces glucocorticoids in response to adrenocorticotropic hormone as part of the hypothalamic-pituitary-adrenal axis, and the innermost zona reticularis produces androgens.
- Much of our understanding about development and homeostasis of the adrenal gland is derived from studies in mice. While the mouse adrenal gland is similar in many respects to the human gland, there are some important differences: (1) the mouse adrenal cortex contains a transient inner zone not found in humans called the "X zone," which is a remnant of fetal cortex, and (2) many strains of mice do not express CYP17A1 after fetal adrenal development. As a result, these animals synthesize corticosterone rather than cortisol as the main glucocorticoid, and they do not produce adrenal androgens.

EMBRYONIC ADRENAL DEVELOPMENT

Overview

The adrenal cortex is derived from the adrenogonadal primordium (AGP), which arises from thickening of the coelomic epithelium. The AGP extends from the dorsal aorta to the dorsal coelomic epithelia of the urogenital ridge.[34] This bipotent cell population serves as a common embryological origin for both the adrenal gland and somatic cells of the gonad. The AGP is identified during development based on the expression of steroidogenic factor 1 (SF-1, encoded by the gene *NR5A1*), which is observed in humans starting at approximately 4 weeks postconception[35,36] and at embryonic day (E) 9 in mice.[37] Cells on the dorsal aorta side progressively separate from the AGP to form the nascent adrenal cortex, while cells on the coelomic epithelial side give rise to the gonadal anlage.[34] AGP separation begins during the fifth week of human gestation or between E10.0 and E10.5 in mice. Following AGP separation, neural crest cells invade the adrenal primordium (~6 weeks human gestation or E13 in mice) to give rise to the adrenal medulla.[38] These cells are initially dispersed but eventually coalesce after birth and differentiate into catecholamine-producing chromaffin cells in the presence of glucocorticoids.[39] Mesenchymal cells encapsulate the gland at approximately 9 weeks of human gestation or E14 to E14.5 in mice,[38,40] and the cortex proceeds with functional zonation and differentiation (Fig. 85.4).

Adrenal Fate Determination

AGP development and specification of the adrenal primordium is dependent upon a number of important factors, including several key nuclear hormone receptors and transcription factors. Because the AGP is a common precursor to both the adrenal and the gonad, disruption of these factors in humans or mice is typically associated with both adrenal and gonadal defects. The nuclear hormone receptors SF-1 and DAX-1 are among the most central and well-studied. Their expression and activity are highly interdependent and must be tightly regulated. In addition, GATA family transcription factors, and particularly the balance between GATA6 and GATA4, helps direct adrenal versus gonadal fate. Following adrenal fate determination, growth factor signaling, including Wnt/β-catenin, sonic hedgehog (SHH), and fibroblast growth factor (FGF), plays a critical role supporting the survival and further progression of the developing gland.

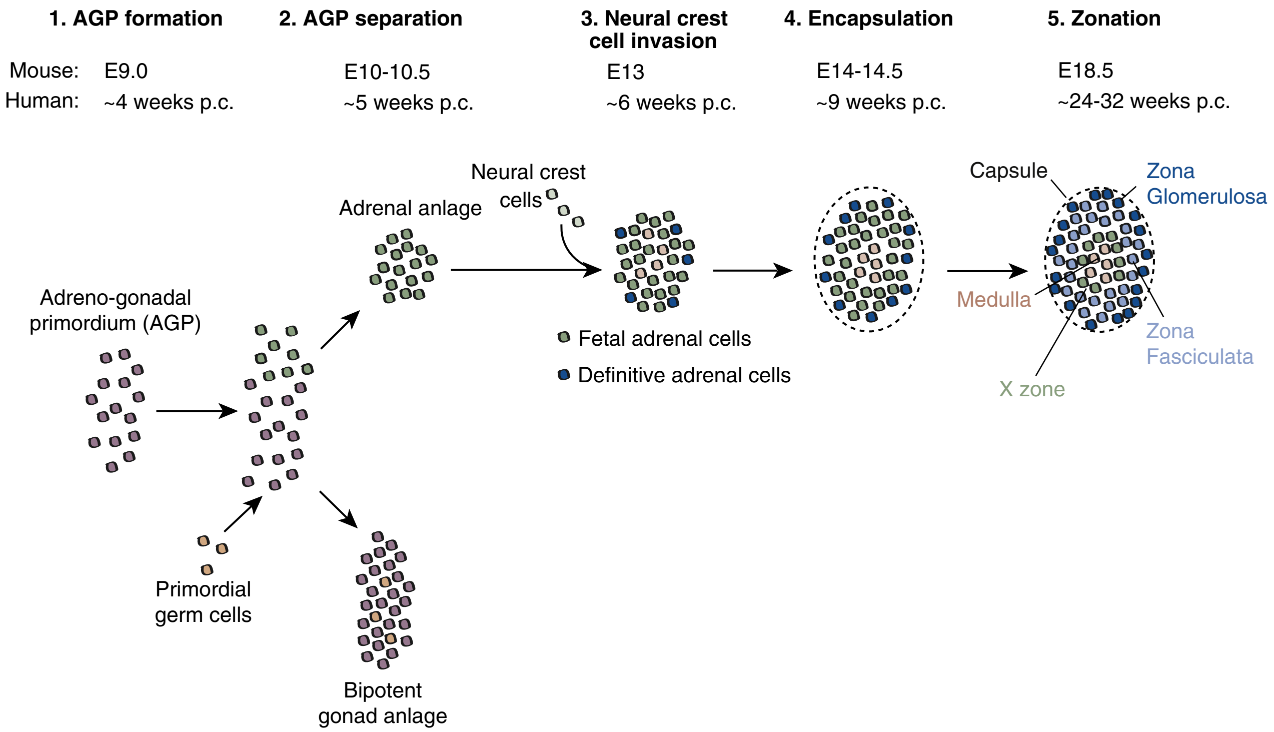

Fig. 85.4 Embryonic adrenal development. The adrenal gland is derived from the adrenogonadal primoridum (AGP). The AGP forms at embryonic day (E) 9 in mouse and ~4 weeks postconception (p.c.) in humans and serves as a common embryological origin for both the adrenal gland and somatic cells of the gonad. Following AGP separation (E10–10.5 in mice, ~5 weeks p.c. in humans), neural crest cells invade the adrenal primordium and ultimately coalescence to form the medulla. The gland is encapsulated by surrounding mesenchyme (E14–14.5 in mice, 9 weeks p.c. in humans) before proceeding with functional zonation and differentiation (E18.5 in mice, ~24–32 weeks p.c. in humans). Fetal adrenal cells give rise to definitive adrenal cells that comprise the adult cortex. In mice, some fetal adrenal cells remain in the cortex and form the X zone, which regresses in males during puberty and in females after pregnancy. (Adapted from Val, P and Swain, A. *Molecular and Cellular Endocrinology.* 2010;323:105–114.)

Steroidogenic Factor 1 (NR5A1). SF-1 (also called adrenal 4 binding protein [Ad4BP]) is a master regulator of steroidogenic cell differentiation. Consistent with its expression early in AGP formation, *Sf-1*-deficient mice fail to develop adrenal glands or gonads and die soon after birth due to adrenal insufficiency.[41,42] Rudimentary structures initially form in *Sf-1* null animals, but adrenal and gonadal tissues are fully extinguished by E13 through apoptotic cell death, suggesting that SF-1 is necessary for the survival of early progenitor cell populations. Importantly, the actual dosage of *Sf-1* gene expression is a critical determinant of adrenocortical growth and differentiation. This is evident in *Sf-1* heterozygous mice, which have significantly smaller adrenal glands compared with controls,[43] as well as impaired compensatory adrenal growth following unilateral adrenalectomy.[44] Consistent with these observations in mouse models, patients with *SF-1* mutations have been found to have a broad spectrum of phenotypes, often including gonadal dysgenesis, and in some cases adrenal insufficiency.[45-48]

Because the dosage of *Sf-1* is critical, tissue-specific enhancers and promoter elements tightly control *Sf-1* activation and expression. Early in AGP formation, a 647-bp fragment in the *Sf-1* promoter is sufficient for its expression.[49] This region contains key Wilm's tumor suppressor (WT1) response elements that are required for WT1-mediated transcriptional activation (see the following section). Following AGP separation, tissue-specific enhancer activity independently maintains *Sf-1* expression in the adrenal and gonad.[50,51] In the adrenal primordium, a regulatory element located in the fourth intron drives expression. This element, termed the fetal adrenal enhancer (FAdE), is highly conserved between mouse and human.[50] However, FAdE shuts off by E14.5 in mouse, and *Sf-1* expression is then maintained in the adrenal cortex by a proposed, but yet to be identified, definitive adrenal enhancer.[52]

Wilm's Tumor Suppressor. Expression of SF-1 in the AGP is directly controlled by WT1.[49] WT1 is a transcriptional regulator expressed early in the urogenital ridge.[29,35,53] Consistent with SF-1 as a direct WT1 target, *Wt1* knockout (KO) mice fail to express SF-1 and display adrenal and gonadal agenesis.[54,55] The ability of WT1 to activate *Sf-1* expression is dependent on a transcription cofactor called Cited2.[56] WT1 and Cited2 act together directly on the *Sf-1* promoter to drive expression above the critical threshold required for adrenal development.[57] However, despite its critical role activating *Sf-1* expression early in AGP formation, WT1 is repressed in the adrenal primordium soon after separation, which is required for further adrenocortical maturation.[29]

While WT1 is not expressed in steroidogenic cells after AGP separation, it is expressed in a high proportion of mesenchymal cells that encapsulate the gland. This population of WT1+ capsular cells was identified experimentally using a tamoxifen-inducible *Wt1:CreERT2* driver combined with the R26R^{mTmG} reporter.[29] This approach permanently labels WT1-expressing cells and their descendants after the administration of tamoxifen. Following tamoxifen at E11.5 and E12.5 (i.e., after AGP separation), a portion of the capsule is green fluorescent protein (GFP)+.[29] Importantly, these capsular WT1+ cells are multipotent and have the capacity to give rise to adrenocortical cells, which can be visualized experimentally using lineage tracing. Tamoxifen injection at E12.5 followed by analysis at E18.5 onwards revealed that GFP-labeled (i.e., WT1-derived) steroidogenic cells (GFP+/SF-1+/WT1-) expand centripetally over time.[29] These capsular WT1+ stem cells contribute at relatively low levels to normal development and homeostasis, but can be activated in response to extreme stress, including gonadectomy[29] (see section on Tissue Stress Progenitors and Adrenal Aging).

DAX-1 (*NR0B1*). One of the most highly studied SF-1-target genes in the developing adrenal is *DAX-1*.[47] This atypical nuclear hormone receptor is expressed in the AGP shortly after the onset of SF-1 expression.[58,59] DAX-1 alters the transcriptional activity of SF-1 in a context-dependent manner, most traditionally through the recruitment of corepressors that function to inhibit steroidogenesis.[60] Mutations in *DAX-1* in humans cause X-linked adrenal hypoplasia congenita, which often presents with adrenocortical failure.[61,62] *Dax-1*-deficient mice initially have a mild phenotype characterized by retention of the X zone.[63] However, loss of *Dax-1* partially rescues *Sf-1* haploinsufficiency,[64] and aged animals display significant adrenocortical dysplasia.[65] These results are consistent with DAX-1 as a key mediator of SF-1-dependent adrenal development and function.

GATA factors. GATA4 and GATA6 are both expressed in the AGP and are essential transcriptional regulators of embryonic development. However, whereas GATA6 expression is maintained in the adrenal cortex throughout development and postpartum, GATA4 expression in steroidogenic cells is extinguished as early as E12.5.[29,66,67] Combined inactivation of both *Gata4* and *Gata6* using *Sf-1:Cre* results in adrenal aplasia.[68] In contrast, mice with isolated inactivation of *Gata6* have adrenal hypoplasia characterized by a thin cytomegalic cortex, overt hypoaldosteronism, and subclinical hypocorticosteronism.[26] A striking observation in these mice is upregulation of GATA4 and gonadal-like markers at the expense of adrenal markers, which is consistent with the idea that GATA6 promotes adrenocortical differentiation, whereas GATA4 drives gonadal differentiation.[69-71] Interestingly, mice lacking the histone methyltransferase EZH2 in steroidogenic cells also show adrenal hypoplasia and glucocorticoid insufficiency.[67] Although GATA6 expression is unaltered in these mice, GATA4 and a number of gonadal differentiation markers (e.g., *Pdgfrα*, *Foxl2*, and *Lhr*) are also markedly upregulated. Altogether, these data demonstrate that the balance between GATA6 and GATA4 expression has a profound impact on adrenal versus gonadal differentiation.

Wnt/β-catenin signaling. Canonical Wnt/β-catenin signaling is one of the main pathways required for early adrenal development. This pathway, which plays an essential role in the development and homeostasis of multiple tissues, relies on extracellular secreted Wnt ligands and the multifunctional protein β-catenin.[72] In the absence of ligands, the cytoplasmic pool of β-catenin is maintained at low levels. This is mediated by phosphorylation of key β-catenin residues by serine/threonine kinases CK1α and GSK3β that are part of the so-called destruction complex, which also comprises the tumor suppressors APC and AXIN. Phosphorylated β-catenin is recognized and ubiquitinylated by the E3 ubiquitin ligase βTrCP, which promotes proteasomal degradation of the protein. This inhibits activation of the pathway by preventing nuclear translocation of β-catenin and stimulation of TCF/LEF-dependent transcriptional activity. Upon Wnt ligand binding to Frizzled (FZD)/LRP5-6 receptor complexes, the destruction complex is sequestered to the plasma membrane, thus preventing phosphorylation and subsequent degradation of β-catenin. Stabilization of β-catenin facilitates its nuclear translocation and interaction with TCF/LEF family members, which triggers expression of canonical Wnt target genes, such as *Axin2*, *Lef1*, or *Apcdd1*.[73-75]

Further levels of fine-tuning of the pathway also exist at the plasma membrane. Specifically, FZD receptors are ubiquitinylated by membrane E3 ubiquitin ligases ZNRF3 and RNF43,[76,77] which are targets of the canonical Wnt pathway.[76] This allows establishment of a negative feedback loop, preventing deregulated pathway activation. This negative regulation mechanism can be counteracted by secreted R-Spondins (RSPOs),[78] which induce membrane clearance of ZNRF3 and RNF43 through both LGR-dependent and LGR-independent mechanisms.[79,80] In addition to the RSPO-ZNRF3/RNF43 signaling module, canonical Wnt/β-catenin activation can also be negatively controlled by other mechanisms, including secreted FZD-related proteins (SFRPs) and (DKKs) glycoproteins.[81]

Activation of canonical Wnt/β-catenin signaling begins early in adrenal development. In mice, immunohistochemistry for β-catenin and TCF/LEF-LacZ reporter activity both demonstrate that signaling is first initiated between E12.5 and E14.5.[82] Pathway activation is highest just beneath the capsule in the underlying zG. Complete inactivation of *Ctnnb1* (the gene encoding β-catenin) using a high efficiency Cre expressed in all SF-1–positive cortical cells (*Sf-1-Cre*^{high})[83] results in severe loss of adrenocortical cells by E14.5 and complete adrenal aplasia by E16.5.[82] These results suggest that canonical Wnt/β-catenin signaling is required for early adrenal development. Interestingly, the converse experiment in which β-catenin is constitutively activated throughout the adrenal cortex early in development results in a similar outcome. Approaches to either directly (*Sf-1-Cre*^{high}*:Catnblox(ex3)* mice) or indirectly (*Sf-1-Cre*^{high}*:Apcfx/fx*) stabilize *Ctnnb1* result in significant adrenal hypoplasia by E16.5.[84,85] These results suggest that the dosage of Wnt/β-catenin activation is critically important for proper adrenal development. Several additional models that alter the level of Wnt activation have been subsequently generated that bypass the early β-catenin-dependent developmental defects and offer insight into the role of Wnt/β-catenin signaling during postnatal adrenal development and homeostasis (see section on Adrenal Cortex Regeneration).

Sonic Hedgehog Signaling. Similar to Wnt/β-catenin signaling, the hedgehog (HH) pathway is a paracrine signaling mechanism driven by secreted factors that is required for the growth and patterning of a wide range of tissues.[86] The three mammalian orthologs, sonic hedgehog (SHH), Indian hedgehog (IHH), and desert hedgehog (DHH), act by binding to the transmembrane receptor Patched1 (PTCH1). In the absence of these ligands, pathway activation is blocked by PTCH1, which represses the transmembrane protein smoothened (SMO). Ligand binding derepresses SMO through PTCH1 inactivation, resulting in intracellular signal transduction and activation of the GLI family of transcription factors. These include GLI1, which is a transcriptional target of active HH signaling and functions in a feedforward loop, as well as GLI2 and GLI3, which are primarily regulated posttranscriptionally. The activation of GLI transcription factors ultimately stimulates a wide range of target genes that promote cell proliferation and help direct tissue patterning.

In the adrenal gland, the HH pathway was first implicated in adrenal development when mutations in *SHH* and other components were identified in patients with holoprosencephaly and Pallister–Hall syndrome.[87-90] These patients have endocrine disorders, including adrenal hypoplasia, which suggested that SHH signaling may be critical for adrenal specification and growth. Consistent with this hypothesis, *in situ* hybridization studies found strong expression of *SHH* mRNA as early as E12.5 throughout the peripheral cortex of the developing gland.[17,91,92] Functional studies targeting *SHH* for deletion throughout the cortex (*Sf-1-Cre*^{high}*:Shhfx/fx*) resulted in significantly smaller adrenal glands in mice, consistent with a critical role for SHH signaling in early adrenal development.[17,92,93] Expanding upon these KO models, lineage-tracing studies further demonstrated that *SHH*-expressing cortical cells in the periphery of the gland give rise to cells of the inner cortex through centripetal migration and differentiation. In these studies, a tamoxifen-inducible *SHH:CreERT2* driver was combined with an enhanced GFP (EGFP)-based lineage reporter to label and track the *SHH* lineage over time.[17] Following the administration of tamoxifen at E14.5, *SHH*-derived steroidogenic cells (EGFP+/SCC+) were observed in the peripheral cortex after 5 days and extended into longer vertical columns by 28 days. These results demonstrate that, during embryonic development, *Shh*-expressing cells help to populate the inner cortex.

Although *SHH* is expressed in the peripheral cortex, its receptor, PTCH1, is expressed in the capsule.[93,94] Consequently, SHH ligands produced in the zG act in a paracrine fashion on capsular cells to activate downstream signaling. Consistent with this paradigm, GLI1, which acts in a feedforward loop to promote active SHH signaling, is also expressed in the capsule.[17,93,94] *Gli1+* capsular cells act as multipotent stem cells to give rise to adrenocortical cells during embryonic development, which has been visualized by lineage tracing experiments. Using *Gli1:CreERT2* combined with an EGFP-based reporter, cortical cells derived from the embryonic Gli1 lineage were tracked over time and found to progressively extend from the capsule into the cortex.[17] Notably, SHH signaling and the GLI1 lineage also significantly contribute to homeostatic maintenance of the adrenal cortex (see section on Adrenal Cortex Regeneration).

Fibroblast Growth Factor Signaling. The FGF signaling pathway is critical for the growth and development of many tissues.[95] The pathway is comprised of 22 secreted FGF ligands and four FGF receptors (FGFRs), with an additional level of complexity through alternative splicing of FGFR1 to 3. Notably, FGFs bind heparan and heparan sulfate, which results in their sequestration to the extracellular matrix. This allows for local release of ligands by heparan sulfate proteoglycans during tissue morphogenesis or in response to injury. Once activated, FGF signaling is generally transduced through activation of RAS/MAP kinase, PI3/AKT, or PLCγ, which promote mitogenic growth, cell survival, and cell migration.

In the developing adrenal gland, all four receptors have been detected,[96,97] along with three primary ligands.[97] These include *Fgf2* and *Fgf9*, which are expressed in the capsule, and *Fgf1*, which is expressed in the cortex. Functional studies have primarily focused on loss of *Fgfr2*, which results in significantly impaired adrenal growth. Mouse models of germline loss of *Fgfr2-IIIb*,[97,98] as well as conditional *Fgfr2* deletion,[15,99,100] consistently show a significant reduction in adrenal size that is often associated with lower rates of proliferation and increased apoptosis. Analysis of glomerulosa structure has further demonstrated that the loss of *Fgfr2* impairs the formation of rosettes and reduces zG function.[15] Together, these studies demonstrate that FGF signaling is critical for adrenocortical cell growth and proliferation, particularly in the early stages of development.

KEY POINTS

- The adrenal cortex is derived from the adrenogonadal primordium (AGP), which separates to give rise to both the adrenal gland and somatic cells of the gonad.
- Following AGP separation, neural crest cells invade the adrenal primordium to give rise to the medulla. These cells progressively coalesce and differentiate into catecholamine-producing chromaffin cells.
- Finally, mesenchymal cells encapsulate the gland and the cortex proceeds with functional zonation and differentiation.
- Proper specification and development of the adrenal gland is dependent upon a number of important factors, including nuclear hormone receptors (e.g., steroidogenic factor 1, Wilm's tumor suppressor, and DAX-1), transcription factors (e.g., GATA4 and GATA6), and growth factor signaling (e.g., Wnt/β-catenin, sonic hedgehog, and fibroblast growth factor).
- The initial adrenal primordium is composed of a large fetal zone that functions to produce high levels of dehydroepiandrosterone, dehydroepiandrosterone sulfate, and cortisol, and a smaller definitive zone that ultimately becomes the adult cortex after fetal zone involution.

Fetal Adrenal Development

Fetal Zone Versus Definitive Zone. The initial adrenal blastema is composed of two distinct zonal compartments: a large region of fetal zone (FZ) cells surrounded by a smaller adult, definitive zone (DZ). In humans, the fetal adrenal cortex grows disproportionately after encapsulation.[38,101] This expansion within the FZ enables the adrenal gland to significantly increase in size (nearly 10-fold), becoming one of the largest organs at term and comparable in size to the kidney. Surrounding the FZ, there is a narrow band of definitive cortex. The DZ initially contains densely packed basophilic cells that are lipid poor. However, these cells are proliferative and begin to accumulate more cytoplasmic lipid after midgestation as they become increasingly steroidogenic. A so-called transitional zone (TZ) takes shape between the DZ and FZ and is capable of producing cortisol. By late gestation, the fetal adrenal begins to resemble the adult cortex, with the DZ and TZ taking on the morphology and function of the zG and zF, respectively. The FZ undergoes involution after birth (see section on Fetal Zone Involution), causing a significant decrease in adrenal weight just after birth.

Function of the Fetal Zone. The FZ is comprised of large eosinophilic cells with high steroidogenic activity. Specifically, FZ cells strongly express CYP17A1, which converts pregnenolone to DHEA. This results in the production of large amounts of DHEA and DHEA-S (up to 200 mg per day) that are then converted by the placenta into estrogens.[101] As the human placenta cannot make estrogens *de novo*, the generation of estrogens through this process is critically important to help maintain normal pregnancy. In addition to DHEA, CYP17A1 also mediates cortisol production in the FZ, which promotes maturation of the fetal organ system. Thus, the FZ primarily functions to produce steroids that help maintain intrauterine development.

Adrenocorticotropic Hormone-Driven Fetal Zone Growth. The principal regulator of fetal adrenocortical development is ACTH. This tropic regulator of the postnatal adrenal cortex is known to promote both hypertrophy and hyperplasia of adrenocortical cells. However, rapid FZ growth predominately results from hypertrophy, whereby the size of each cell rather than the number of cells increases.[101]

Unexpectedly, rather than increasing during FZ expansion, plasma ACTH levels decrease by nearly 50% during prenatal adrenal development.[102] This paradox is partially explained by the progressive sensitization of FZ cells. While not maximally sensitive initially, FZ cells become more ACTH-responsive over time through mechanisms that include increased expression of the ACTH receptor (and thus enhanced ACTH binding capacity).[103,104] This adaptive ACTH response is thought to help prepare the fetus for the stress of birth and postnatal development by increasing the steroid-producing capacity of the FZ.

POSTNATAL ADRENAL DEVELOPMENT

Fetal Zone Involution

Human Adrenal. The first notable event in postnatal adrenals is the rapid involution of the FZ, followed by progressive expansion and zonation of the adult definitive cortex (Fig. 85.5). Whereas the FZ

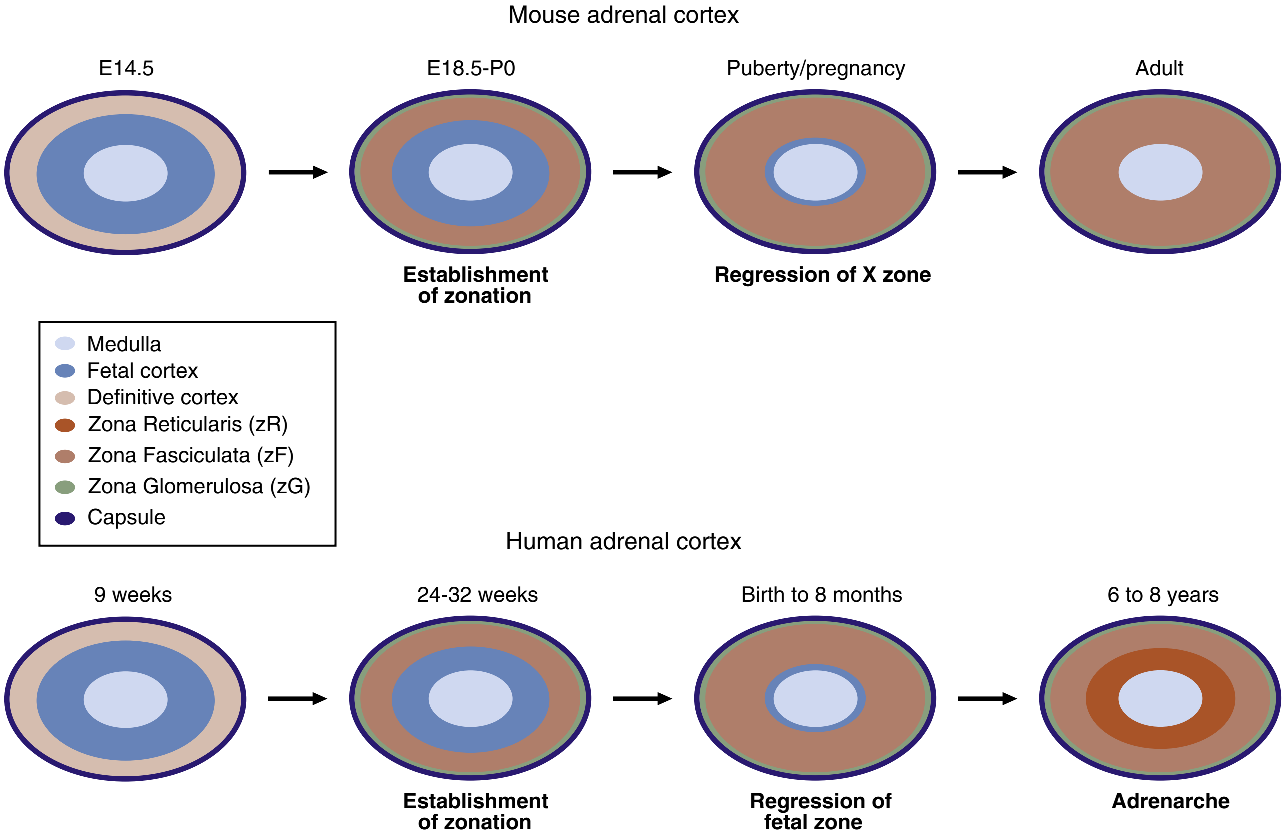

Fig. 85.5 **Pre- and postnatal adrenal development in mice and humans.** Functional zonation of the adrenal cortex starts at embryonic day 18.5 in mouse and between 24–32 weeks in humans. Whereas the fetal zone immediately regresses in humans after birth, its regression is delayed until puberty in male mice or first pregnancy in female mice. In human adrenals, zona reticularis develops during adrenarche (6–8 years), between the zona fasciculata and the medulla. There is no zona reticularis in the mouse adrenal cortex.

represents up to 70% of total adrenal volume at birth (up to 85% of the cortex), it only takes up 3% of the gland after 8 months.[105] FZ involution is evident immediately after birth and can be divided in two phases.[105,106] The first phase is characterized by rapid regression of FZ until the end of the second week postpartum. This phase is associated with hemorrhage and high levels of apoptosis, which is maximal during the second week of life (30% of FZ cells). The second phase is characterized by slower involution and relatively constant levels of apoptosis (20% of FZ cells). The FZ mainly synthesizes androgens, and during fetal life, concentrations of DHEA follow the increase in FZ size in the last two trimesters of pregnancy.[107] Following FZ involution, adrenal androgen levels rapidly decline until the onset of adrenarche at around 6 to 9 years.[108,109] The mechanisms involved in FZ regression in the human adrenal gland remain elusive. Early reports showed that levels of plasma DHEA-S and urinary 3β-OH-5ene steroids remained elevated for many weeks following parturition in preterm babies, consistent with persistence of the FZ in this context. This suggested that FZ involution was controlled by the duration of gestation rather than by parturition itself.[110] However, more recent evidence relying on ultrasonography and measurement of serum cortisol and androstenedione concentrations reported similar adrenal involution, and endocrine activity in preterm and full-term babies.[109] This suggests that parturition itself triggers FZ involution.

A number of factors have been proposed to control human FZ maintenance and involution (Fig. 85.6). Anencephalic fetuses display marked adrenal atrophy, and *in vitro* treatment of human fetal adrenal cells with ACTH stimulates their growth and endocrine activity.[111–115] Although fetal ACTH is required to support normal FZ growth and activity during fetal life, there is no decrease in ACTH at the time of FZ involution,[110,115] suggesting that this process is dependent on other mechanisms. Experimental evidence suggests involvement of transforming growth factor β (TGFβ) signaling, and in particular of activins and inhibins, in this process. These are peptide hormones formed by the dimerization of α, βA, and βB inhibin subunits, encoded by three distinct genes. Activins A or B are formed by homodimerization of βA or βB subunits, respectively, whereas inhibins A or B are formed by heterodimerization of α subunits with either βA or βB subunits, respectively. Activins signal through ACVRI and ACVRII activin receptors, which results in phosphorylation of SMAD2 and SMAD3. These interact with SMAD4 and migrate to the cell nucleus, where they trigger expression of target genes that can be involved in apoptosis. Inhibins, on the other hand, can sequester ACVRII by interacting with betaglycan. This results in inhibition of activin signaling.[116] βA and βB subunits are expressed throughout human adrenal cortex, with predominant expression in zG, whereas the α subunit is mostly found in the zR and in the fetal adrenal.[117-120] ACVRI/II receptors and betaglycan are expressed in the adult and fetal adrenal cortex.[121] Fetal adrenal cells also express SMADs3/4/6/7, suggesting that inhibin/activin signaling may play a role in FZ involution. Consistent with this idea, TGFβ and activin A were shown to specifically inhibit growth and induce apoptosis of human FZ cells in culture.[106,118,122] This suggests that these TGFβ/activin/inhibin family members may play a role in FZ involution. However, this would require induction of activin signaling in the human fetal adrenal after birth. Interestingly, evaluation of

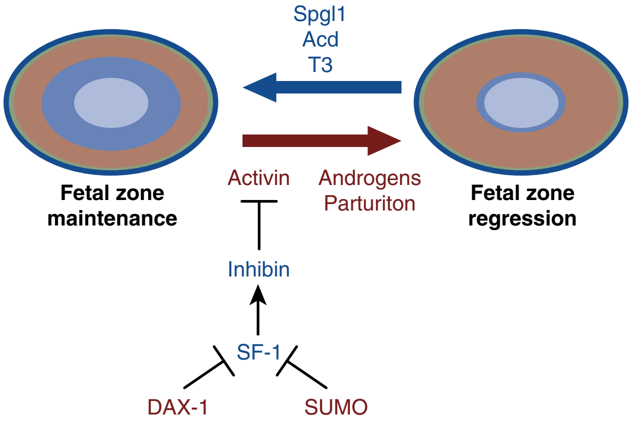

Fig. 85.6 **Factors involved in maintenance or regression of the fetal cortex.** Hormonal manipulations and mouse genetics have shown that activins, androgens, and parturition favor fetal cortex regression. This can be counteracted by inhibin, which can be stimulated by steroidogenic factor 1 (SF-1). This effect of SF-1 is inhibited by its sumoylation and by the antagonistic activity of DAX-1. In contrast, Spgl1, Acd, and triiodothyronine may be involved in maintenance of the fetal cortex. Most of the molecular mechanisms involved in these processes remain elusive.

activins and inhibins in the artery and vein of the umbilical cord of term infants showed that the placenta was the major source of inhibin B, whereas the fetus was the main producer of activin A.[123] It is therefore tempting to speculate that parturition, by removing a major source of inhibin, could alter the activin/inhibin ratio to favor activin signaling and FZ involution. Although these mechanisms are difficult to study in humans, studies in mouse models have provided further insight into potential regulators of FZ homeostasis (Fig. 85.6).

Mouse Adrenal. The mouse X zone (see section on Mouse X Zone and Rat Undifferentiated Zone) is exclusively derived from fetal adrenal cells that express the fetal enhancer of *Sf-1*,[24,50,124] and may thus be the mouse equivalent to the human FZ. However, it does not express CYP17,[20] which does not allow production of adrenal androgens. Rather, the X zone is characterized by expression of 20αHSD,[25] which appears at around 3 weeks of life.[25,125,126] Another key feature that distinguishes X zone from the human FZ is the kinetics of its involution (Fig. 85.5). Indeed, whereas the FZ regresses postnatally in both sexes in humans, X zone involution is observed after around 4 months or during the first pregnancy in females and after puberty in males.[23,25,127]

Role of Sex Hormones and Prolactin. The sexual dimorphism associated with X zone regression suggested an involvement of sex hormones in this phenomenon. Indeed, injection of testosterone propionate or the nonaromatizable androgen dihydrotestosterone (DHT) to nulliparous adult females results in X zone regression, which can be reversed upon removal of DHT after 7 days of treatment. Conversely, gonadectomy in prepubertal males prevents X zone regression and results in growth of a secondary X zone in postpubertal males.[23,25,128,129] This indicates that androgens, but not estrogens, directly induce involution of the X zone in male mice at puberty. These observations have been further confirmed by the targeted ablation of the androgen receptor (AR) in steroidogenic cells of the adrenal cortex, which resulted in a dramatic reduction in apoptosis and X zone maintenance in male adrenals at puberty. Interestingly, AR ablation resulted in maintenance of a larger X zone than castration alone, suggesting that AR may exert androgen independent effects on X zone homeostasis[129] (Fig. 85.6).

The mechanisms associated with X zone regression during pregnancy are a lot more elusive. Concordant observations have shown a rapid decline in 20αHSD activity and morphological X zone during pregnancy, which are not restored after parturition.[23,25,125,127] Ovariectomy is associated with transient X zone thickening,[130] and progesterone injection induces rapid regression of the X zone.[125,131] However, this effect is only observed in females with intact ovaries,[131] suggesting that the effect of progesterone is dependent on its conversion to androgens by the ovary, particularly during pregnancy.[132] Consistent with this, testosterone peaks at 9 days postcoitum (dpc), which is coincident with onset of X zone regression between 8 and 12 dpc in gravid females.[25,133] Induction of pseudopregnancy by mating female mice with vasectomized males has no effect on X zone morphology and 20αHSD activity, compared with nulliparous females.[25] This suggests that the elevation of progesterone and estrogens induced during the first 8 days of pseudopregnancy is not sufficient to trigger the first phases of X zone involution, even though hormonal levels are comparable with pregnancy. Interestingly, removal of pups, which results in decreased prolactin secretion in deprived dams, is associated with partial recovery of 20αHSD activity and partial regrowth of the X zone.[25] This suggests that the rise in prolactin secretion during pregnancy and before weaning may be involved in X zone involution. However, prolactin injection to nulliparous females has no impact on X zone homeostasis. Similarly, inactivation of STAT5 signaling pathway, which plays a central role in prolactin response, has no impact on the X zone of either males or females.[25] Altogether, these data suggest that the prolactin increase induced by suckling may have an impact on X zone involution in primiparous females, but does not significantly contribute to regression during pregnancy or at puberty in males.

Role of Thyroid Hormones. Thyroxin and thyroid extracts induce enlargement of a histological X zone in the adrenal cortex of mice.[134,135] Conversely, hypothyroid *Hyt* mutant mice that harbor a mutation of the thyrotropin receptor, have a poorly developed X zone,[136] suggesting that thyroid hormones and their receptors may play a role in X zone homeostasis. Recent evidence, based on a LacZ reporter inserted at the *Thrb* locus, showed that thyroid hormone receptor beta 1 (TRβ1) is expressed in mouse inner adrenal cortex from E14.5 into the postnatal period. Its expression pattern is reminiscent of and partly overlaps with that of 20αHSD. However, it is more broadly expressed, expanding in the inner zona fasciculata, and although it declines in males by postnatal day 28, it persists after pregnancy in females. Interestingly, hormonal treatments at different time points showed that triiodothyronine (T3) could accelerate appearance of the 20αHSD+ zone after birth, induce hypertrophy of the X zone before puberty, and counteract X zone regression at puberty in males, although it could not induce regeneration after regression.[126] Analysis of *Thrb*-deficient mice showed that these effects of exogenous T3 were dependent on the thyroid hormone receptor. However, *Thrb-/-* adrenals were indistinguishable from wild-type at baseline.[126] Although this may reflect compensation by other thyroid hormone receptors, it suggests that thyroid hormones are not required for normal development of the X zone, but that they may be involved in modulating its homeostasis and function. Whether this has relevance to the human fetal adrenal cortex is currently unknown.

Role of Activin/Inhibin Signaling. Consistent with findings in human adrenals, the activin/inhibin/TGFβ signaling pathway may also control fetal adrenal cell growth in mouse adrenals (Fig. 85.6). Indeed, all four subunits of activin receptors (ACTR-IA, ACTR-IB, ACTR-IIA, and ACTR-IIB) are expressed in the mouse adrenal cortex, and ACTR-IA, ACTR-IIB, and SMAD2, an essential component of the TGFβ signaling pathway, are expressed more specifically in the X zone.[137] Interestingly, activin treatment has a specific growth inhibitory effect on primary cultures of adrenals containing X zone cells and is able to induce apoptosis in the presumptive X zone of whole adrenals in culture.[137] The potential role of activin in controlling X zone homeostasis is further supported by accelerated X zone regression in inhibin-deficient mice that show increased levels of gonadal and adrenal activin secretion.[137,138] This effect is counteracted by gonadectomy, which induces unrestricted growth of presumptive X zone cells and SMAD3-dependent adrenal cortex tumor development.[137,139] However, there is no reported adrenal gland phenotype in mice deficient for activin.[140]

Genetic Models Associated with Failure to Develop an X Zone.

A number of genetically engineered or mutant mice display X zone aplasia. The adrenocortical dysplasia gene (*ACD*) encodes TPP1, which plays a central role in telomere protection within the TRF1 complex.[141] Mice harboring a spontaneous homozygous splice donor mutation in the *Acd* gene display multiple developmental defects, including cytomegalic adrenocortical dysplasia and glucocorticoid insufficiency. They are also characterized by X zone aplasia.[142,143] Adrenal aplasia is associated with massive induction of cellular senescence and can be partly reversed by genetic inactivation of *Tp53.*[144] However, it is unclear if reduction of senescence following *Tp53* inactivation also rescues X zone differentiation.[144]

Sgpl1 mutant mice also show X zone aplasia.[145] *Sgpl1* encodes the enzyme responsible for the last step of sphingosine 1 phosphate (S1P) catabolism, which works as a signaling molecule. Interestingly, SGPL1 is expressed in the human fetal adrenal (from Carnegie stage 19 onwards) in both the FZ and DZ. In the adult adrenal, SGPL1 expression is found throughout the cortex, but is more concentrated in the zR. Besides X zone aplasia, *Sgpl1-/-* mice also show altered cortical zonation and atrophic zF, associated with lower CYP11A1 and CYP11B2 expression. This is consistent with the primary adrenal insufficiency observed in patients with homozygous inactivating mutations in *SGPL1.*[145,146] The molecular mechanisms underpinning adrenal insufficiency and X zone aplasia in this context are unclear. However, *Sgpl1* inactivation results in accumulation of S1P,[145,147] which can be converted back to sphingosine by S1P phosphatases. Whereas S1P has been shown to stimulate steroidogenesis in H295R cells in culture,[148] sphingosine is an inhibitory ligand for SF-1 and acts to maintain it in an inactive conformation.[149,150] This suggests that alterations of SF-1 activity may be involved in X zone homeostasis (Fig. 85.6).

Genetic Models Associated with Persistent X Zone. Activity of the nuclear receptor SF-1, the master regulator of steroidogenic tissues development and differentiation,[151] can be regulated by a number of posttranslational modifications, including phosphorylation,[152] acetylation,[153] and sumoylation.[154-156] This modification, which consists in the reversible addition of SUMO modules on two lysine residues of SF-1 (K119 and K194), does not have a global effect on SF-1-mediated transcription, but rather dampens recognition of a subset of SF-1 target genes, coined SUMO-sensitive targets, which are essentially transcribed when SF-1 is hyposumoylated.[156] *In vivo*, the replacement of the two lysine residues by nonsumoylatable arginine residues, through homologous recombination (SF-1^{2KR}), results in abnormal adrenal development. This is characterized by aberrant expression of gonadal markers (*Sox9*, *Amhr2*, *Aldh1a1*), upregulation of HH signaling, hypoaldosteronism, and persistence of a 20αHSD-positive X zone after puberty, even though it eventually regresses later in life.[157,158] Although the molecular mechanisms underlying persistence of the FZ were not evaluated in this model, previous data had shown that inhibinα is a SUMO-sensitive target of SF-1, the expression of which is upregulated by nonsumoylatable SF-1 mutants.[156] This may account for an imbalance in activin/inhibin signaling that would prevent normal apoptosis of the X zone (Fig. 85.6).

DAX-1 is an atypical non-DNA-binding nuclear receptor that has been shown to repress SF-1 transcriptional activity[159-161] (see section on DAX-1 (*NR0B1*)). DAX-1 mutations in patients are associated with X-linked adrenal hypoplasia congenita (AHC).[61,62] Patients with AHC present with neonatal adrenal insufficiency associated with cytomegalic hypoplastic adrenals.[162] Surprisingly, mice with *Dax-1* gene ablation have no signs of adrenal insufficiency in early life, but show temporary persistence of the X zone after puberty.[63,158] Interestingly, analysis of the fetal adrenal lineage using the fetal adrenal enhancer of *Sf-1* to drive expression of a LacZ reporter gene (*FAdE:LacZ*) shows persistence of FAdE activity in 20αHSD+ cells of both *Sf-12KR* and *Dax-1* KO adrenals, confirming their fetal rather than adult origin.[158]

Altogether, these data suggest that stimulation of SF-1 transcriptional activity, either by inhibiting its sumoylation or by inactivation of a key repressor, can result in temporary persistence of the X zone. Regression of the X zone may thus be mediated by inhibition of SF-1 activity (Fig. 85.6). In cell culture, sumoylation of SF-1 can increase interactions between SF-1 and DAX-1, resulting in almost complete inactivation of *Sf-1* fetal enhancer activity.[158] This may provide a mechanism that would explain extinction of *Sf-1* expression in fetal adrenal cells, resulting in their death, consistent with the role of SF-1 in the survival of steroidogenic cells.[41,163,164] The recent observation that PKA signaling inhibits sumoylation in the adrenal cortex may add another level of control to these processes.[165]

KEY POINTS

- The fetal cortex regresses after birth in both mouse and human. Whereas human fetal cortex regresses immediately after birth, regression is delayed until puberty in male mice and after the first pregnancy in female mice.
- Involution of the fetal cortex involves apoptosis and is mostly controlled by activin/inhibin/transforming growth factor β signaling. This may also involve sex hormones, particularly in mice.
- Genetically engineered mouse models show that tampering with SF-1 dosage has a key role in controlling homeostasis of the fetal zone.
- Lineage-tracing studies in mice have shown that the definitive cortex, which takes over the entire gland after fetal zone regression, originates from cells of the fetal cortex during embryonic development.

Origin of the Definitive Cortex. Lineage-tracing studies relying on FAdE have shown that most of the definitive cortex is derived from FAdE+ fetal adrenal cells at E11.5. However, the capacity of FAdE+ cells to give rise to adult cells is lost after E14.5.[24,50] Stronger expression of DAX-1 in cells of the definitive cortex is thought to play a role in the extinction of FAdE in this lineage. In these cells, *Sf-1* expression is potentially maintained through mobilization of an adult enhancer that has yet to be identified.[24,50] In addition, analysis of the role of SHH signaling in the adrenal cortex showed that SF-1-/GLI1+ capsular cells could give rise to some definitive cortical cells at E14.5 and onwards, albeit with low efficiency.[17,93] Further lineage-tracing studies suggest that a very small subset of SF-1-/GLI1+ cells (~7%) may be derived from FAdE+ cells.[166] However, such capsular lineage is not found with *Sf-1-Cre*, suggesting that this may be the result of ectopic expression of the short FAdE construct. Altogether, these observations suggest that both fetal SF-1+/FAdE+ and capsular SF-1-/GLI1+ cells can give rise to the definitive cortex. Whether similar mechanisms also exist in human adrenals is unknown, but the high conservation of FAdE sequences in humans is in support of this hypothesis.

Establishment of Adrenal Cortex Zonation

Functional zonation is established in cells of the definitive cortex in the perinatal period. It manifests as the establishment of three (primates) or two (most rodents) concentric zonae with distinct histological and functional features, that undertake the endocrine activity of the gland[167] (see section on Adrenal Cortex). In rodents' adrenals, zonal restriction of steroidogenic enzymes expression is established during embryonic development. CYP11B1 (zF) is expressed in the entire cortex from E13.5 onwards. In contrast, CYP11B2 and angiotensin receptor AT1b (zG) are expressed at the periphery of the gland after E18.5 (Fig. 85.5). At this stage, CYP11B1 and CYP11B2 are expressed in mutually exclusive areas of the cortex.[17,168-170] In human adrenals, steroidogenic enzymes responsible for glucocorticoids and androgens synthesis are readily detected during the first trimester, mostly in the fetal and transition zones. Their expression markedly increases during the second trimester, concomitant with increased production of glucocorticoids.[171-173] Consistent with the lack of aldosterone production during the first and second trimester,[172] CYP11B2 appears in the DZ at 24 weeks of gestation and is maximal at 32 weeks[172,174] (Fig. 85.5). Establishment of these zonal expression patterns is the basis for functional adult adrenal cortex zonation, which is maintained throughout life.[169,175-177] Genetic and cell lineage tracing studies in mouse models have allowed understanding of the molecular mechanisms involved in establishing and maintaining these differentiation patterns at homeostasis and in response to hormonal stimuli and cell renewal.

Differentiation of Zona Glomerulosa. Ang II and plasma potassium concentrations are the main regulators of zG endocrine activity.[178] Activation of the renin-angiotensin system following hyponatremia or hyperkaliemia induces a rapid expansion of zG, an increase in the number of CYP11B2+ cells, and an induction of CYP11B2 expression, allowing for increased aldosterone secretion. Conversely, inhibition of the renin-angiotensin system using drugs such as Captopril results in a rapid atrophy of zG.[179-181] However, mice deficient for the two type I receptors of Ang II (*Agtr1a-/-;Agtr1b-/-*) have normal adrenal histology.[182] This indicates that Ang II signaling is not involved in the establishment and initial differentiation of zG, even though it plays a central role in remodeling the zone to modulate the supply of mineralocorticoids. Consistent with this idea, ectopic chemogenetic activation of Gαq signaling, which is downstream of angiotensin receptors, results in ectopic expression of CYP11B2 within the zF and increased renin-independent aldosterone production.[183]

Over the last decade, analysis of genetically engineered mouse models has allowed identification of the canonical Wnt/β-catenin signaling pathway as one of the key regulators of zG differentiation and homeostasis[15,85,184-186] (Fig. 85.7). Whereas β-catenin is activated throughout the developing adrenal cortex at E12.5, its activity is highest in the presumptive zG by E18.5.[82] In the adult, β-catenin is expressed and accumulated at high levels throughout the zG.[82,85,184,185] This area is also characterized by accumulation of the Wnt targets LEF1 and AXIN2 and by expression of Wnt reporter constructs.[82,85,184,185] This suggests that strong Wnt pathway activation in zG cells may play a role in the differentiation of this zone.

Consistent with this idea, conditional inactivation of *Ctnnb1* (the gene encoding β-catenin) within zG cells, using *Cyp11b2-Cre* as the driver, results in smaller and morphologically altered glomeruli.[15] Conversely, constitutive activation of β-catenin within CYP11B2+ cells (*Cyp11b2-Cre* driver) results in continuous expansion of zG, increased rosette frequency, and a significant increase in plasma aldosterone (albeit without renin suppression).[15,186] This is further confirmed by stochastic activation of β-catenin throughout the entire cortex (*Akr1b7-Cre*), which results in zG expansion, ectopic differentiation of scattered zG cells within the zF, and elevated plasma aldosterone levels.[85,187] The observation of primary aldosteronism in these models suggested that deregulated Wnt pathway activity could be involved in hyperaldosteronism in patients. Consistent with this idea, 33/47 patients with aldosterone-producing adenomas (APA) had constitutive Wnt pathway activation.[188] This can result from activating mutations of *CTNNB1*, found in approximately 5% of APA patients[189,190] or from downregulation of Wnt inhibitors such as SFRP2.[188] Altogether, these data show that β-catenin signaling plays a central role in zG differentiation. Mechanistic investigations have shown that β-catenin, either directly or indirectly through NURR1 and NUR77 nuclear receptors, stimulates transcription of *CYP21*, *CYP11B2,* and *AT1R.*[188] This provides an explanation for increased aldosterone production following Wnt pathway activation. However, this does not account for increased rosette formation. Interestingly, the growth factor receptor FGFR2 is upregulated in response to constitutive β-catenin activation and its genetic inactivation in CYP11B2+ cells disrupts rosette morphology and frequency.[15] This suggests that FGF signaling may play a role downstream of Wnt signaling to establish the specific three-dimensional structure of the zG.

How is Wnt/β-catenin activated to allow for zG differentiation? A number of Wnt ligands, including WNT2b, WNT4, WNT5a, WNT5b, WNT9a, and WNT11, are expressed at the periphery of the adrenal cortex during embryonic development and/or in the adult adrenal.[85,184,185,191] However, only the role of WNT4 has been extensively studied so far (Fig. 85.7). It is expressed in the developing adrenal glands of mice as early as E11.5 and shows restricted expression at the periphery of the cortex by E14.5[192] and within zG in the adult adrenal,[85] suggesting that it may be involved in zG differentiation. Indeed, full-body ablation of *Wnt4* is associated with reduced zG differentiation and decreased plasma aldosterone concentration.[192] This is further confirmed by conditional ablation of *Wnt4* in adrenal steroidogenic cells using *Sf-1-Cre.*[85,184] A role for WNT4 in human adrenals is suggested by the observation that patients with mutations in *WNT4* associated with SERKAL (SEx Reversion, Kidneys, Adrenal and Lung dysgenesis) syndrome have signs of adrenal dysgenesis.[193] Conversely, overexpression of WNT4 in human adrenocortical H295R cell lines induces CYP11B2 expression and aldosterone production.[194]

Another important aspect of Wnt pathway control is modulation of FZD receptor availability at the plasma membrane. This involves the membrane E3 ubiquitin ligases ZNRF3 and RNF43 that target FZDs for degradation[76,77] and the RSPOs (RSPO1–4) that antagonize ZNRF3 and RNF43 by inducing their membrane clearance.[79,80,195] *Rspo3*, and to a lesser extent *Rspo1,* are expressed in the adrenal capsule,[184,185] and genetic ablation of *Rspo3* in the capsule results in a marked reduction of Wnt pathway activity and zG differentiation, associated with decreased expression of WNT4.[184] This suggests that RSPO3 from the capsule plays a key paracrine function to stimulate Wnt signaling in the underlying zG (Fig. 85.7). Whereas RNF43 is barely detectable in the adrenal, ZNRF3 is expressed throughout the cortex.[185] Consistent with its low level of expression, adrenal-specific ablation of *Rnf43* does not alter adrenal homeostasis. In contrast, mice with *Znrf3* inactivation show robust hyperproliferation and hyperplasia, resulting in a nearly 8.5-fold increase in adrenal size by 6 weeks. This phenotype can be significantly reversed by ablation of Porcupine (*Porcn*), which is an enzyme required for Wnt ligand secretion, indicating that the hyperplasia is at least in part Wnt-dependent. However, in contrast to mice bearing constitutive activation of β-catenin, there is no alteration of zonation patterns, and the hyperplasia is focused on zF rather than

Fig. 85.7 **Pathways involved in functional zonation of the adrenal cortex. A,** WNT signaling and adrenocorticotropic hormone (ACTH) signaling control differentiation of the zona glomerulosa (zG) and zona fasciculata (zF), respectively. Schematic representation of the mouse adrenal cortex. Canonical WNT signaling pathway activated by WNT4 (produced by zG cells) and RSPO3 (produced by capsule cells) stimulates differentiation of the zG and production of aldosterone. ACTH/cAMP/PKA signaling pathway stimulates differentiation of the zF and production of corticosterone in rodents or cortisol in humans. AT1R and CYP11B2 are specifically expressed in the zG, whereas MC2R, MRAP, and CYP11B1 are specifically expressed in the zF. **B,** Molecular mechanisms of zG differentiation. In the zG, canonical WNT signaling is activated by RSPO3, which inhibits the membrane E3 ubiquitin ligase ZNRF3, preventing degradation of Frizzled (FZD) receptors. This allows stimulation of FZD by WNT4 produced within the zG, which results in accumulation and nuclear translocation of β-catenin (β-cat). β-catenin, by interacting with LEF/TCF transcription factors, stimulates expression of its target genes, including WNT4. This results in reinforcement of WNT pathway activation within zG cells. β-catenin also stimulates expression of AT1R, allowing response to Angiotensin II, of CYP21 and of the zG-specific CYP11B2 to allow production of aldosterone. This is achieved directly (AT1R and CYP21) and indirectly (CYP11B2 and CYP21) through stimulation of NURR1 and NUR77 expression (NURs). ZNRF3 is also a direct target of β-catenin, which ensures a negative feedback on WNT pathway activation to maintain tightly controlled levels of activation. **C,** Molecular mechanisms of zF differentiation. Expression of MC2R and the accessory protein MRAP allows response of zF cells to pituitary ACTH. This induces recruitment of the Gα protein to the adenylate cyclase, which converts ATP to cAMP. By binding to the regulatory subunits of PKA (R), cAMP allows release of the catalytic subunits (C), which phosphorylate the transcription factor CREB. Phosphorylated CREB migrates in the nucleus, where it stimulates transcription of a number of steroidogenic enzymes, among which the zF-specific CYP11B1, which allows production of corticosterone (mouse) or cortisol (human).

zG.[185] This is correlated with normal, high levels of Wnt activation in the zG. *Znrf3-/-* adrenals instead display sustained low Wnt pathway activity throughout the zF. Moreover, heterozygous inactivation of *Ctnnb1* partially rescues the hyperplastic phenotype. These results suggest that, whereas high levels of canonical Wnt signaling achieved by direct β-catenin stabilization primarily drive zG differentiation, and to a lesser extent hyperproliferation, moderate levels resulting from *Znrf3* inactivation promote proliferation and are not sufficient for glomerulosa differentiation. This is consistent with the observation of moderate Wnt activation and high levels of proliferation in the normal outer zF.[185]

Differentiation of Zona Fasciculata. The pituitary hormone ACTH is a key regulator of zF differentiation. It acts through MC2R and the accessory protein MRAP, which are expressed at higher levels in the zF compared with the zG, to stimulate cAMP/PKA signaling.[196-198] In turn, PKA through direct phosphorylation of CREB, and indirect effects on SF-1 and some other transcription factors, stimulates expression of zF-specific genes such as *CYP11B1*, *Akr1b7*, or *HSD11B2*[199-201] (Fig. 85.7). Consistent with a specific role of ACTH/cAMP/PKA signaling in zF differentiation, chronic administration of ACTH induces hypertrophy of zF and increases glucocorticoid secretion, whereas dexamethasone administration induces zF atrophy and inhibition of glucocorticoid production, without alteration of zG.[124,202-204] In further support of this concept, mutations in either *MC2R* or *MRAP* in patients are associated with zF degeneration and unresponsiveness to ACTH, resulting in familial glucocorticoid deficiency.[197,205,206] The key role of the ACTH/cAMP/PKA pathway in zF differentiation is further confirmed by massive hypoplasia of the zF and failure to produce glucocorticoids in *Pomc*, *Mc2r,* and *Mrap* KO mice.[207-210] Although *Pomc* and *Mc2r* KO mice also have mild mineralocorticoid insufficiency, consistent with a minor role of ACTH in acutely controlling aldosterone secretion,[211] *Mrap* KO mice have normal circulating aldosterone levels.[210] This suggests that MRAP plays a more zF-specific role in the ACTH response. Isolated glucocorticoid insufficiency and aberrant zF differentiation are also observed in mice with adrenal-specific ablation of the histone-methyltransferase EZH2, which results in overexpression of phosphodiesterases PDE1B, 3A, and 7B, and a subsequent reduction in cAMP/PKA signaling.[67] At the other end of the spectrum, patients with inactivating mutations of the regulatory subunit RIα of PKA (encoded by *PRKAR1A*)[212] or of the phosphodiesterases PDE11A[213] and PDE8B[214] have increased cAMP/PKA signaling, which is associated with hypercortisolism and ACTH-independent Cushing syndrome.[215] This is also the case for patients with activating mutations of the α-subunit of the Gs protein (encoded by *GNAS1*)[216] or of the catalytic subunit of PKA (encoded by *PRKACA*).[217] In most cases, the endocrine defect is restricted to hyperproduction of cortisol, confirming the prominent role of PKA signaling in zF differentiation and homeostasis. Consistent with this idea, mice with conditional ablation of *Prkar1a* in the adrenal cortex have expansion of zF and autonomous corticosterone production.[85,128,218] Similarly, *Pde8b* KO mice have elevated urinary corticosterone, as a result of hypersensitivity to ACTH stimulation.[219]

Differentiation of Zona Reticularis. Adrenarche, which occurs between 6 and 8 years in humans, corresponds to a marked increase in DHEA and DHEA-S production by cells of the zR, which is morphologically apparent by 3 years of age but only reaches its maximum size at around 13 years.[22,220,221] The molecular mechanisms that control differentiation of zR remain elusive. Interestingly, constitutive activation of PKA, resulting from conditional inactivation of *Prkar1a* in cells of the definitive cortex, results in development of a reticularis-like zone in genetically engineered mice.[128] Indeed, in contrast to wild-type mice, which do not develop any zR features, *Cyp11b2-Cre;Prkar1afl/fl* mice express high levels of CYP17 in cells located between the zF and medulla and produce cortisol, DHEA, and DHEA-S, which are normally not found in mice. As in humans, this is associated with high levels of CYB5 and low levels of HSD3B expression in the reticularis-like zone.[128] This suggests that increased PKA activity may be sufficient to trigger zR development. This is consistent with data showing that dexamethasone can suppress adrenal androgens production[222-224] and failure of adrenarche in children with ACTH receptor deficiency.[225] However, there is no evidence of a concomitant rise in DHEA and ACTH levels during adrenarche,[226-228] suggesting that some other, unidentified factors may trigger zR differentiation.

KEY POINTS

- Functional zonation of the adrenal cortex is established perinatally by zone-restricted expression of Angiotensin II receptor (zona glomerulosa), MC2R/MRAP (zona fasciculata), CYP11B2 (zona glomerulosa), and CYP11B1 (zona fasciculata).
- Zona glomerulosa differentiation is dependent on canonical WNT/β-catenin signaling and is modulated by Angiotensin II.
- Zona fasciculata differentiation is dependent on adrenocorticotropic hormone/cAMP/PKA signaling.
- The mechanisms involved in zona reticularis differentiation remain elusive, although the process may involve PKA signaling.

MAINTENANCE OF ADULT ADRENAL CORTEX FUNCTION BY CORTICAL CELL RENEWAL

Function of the adult adrenal cortex is maintained throughout life by a constant renewal process relying on stem and progenitor cells in the outer capsule and peripheral cortex, centripetal cell migration, and sequential differentiation of migrating cells as a function of their position along the corticomedullary axis[167] (Fig. 85.8). Some of the first evidence for the presence of progenitor cells within the capsule and outer cortex was provided by experiments showing that, following rat adrenal enucleation, remaining tissues were able to form a fully differentiated and hormonally active cortex after autotransplantation to the ovary.[229,230] This suggested that adrenal cortex progenitor cells were present in the capsular/subcapsular compartment. Consistent with this, most proliferation was observed in the outer cortex and could be strongly stimulated by unilateral adrenalectomy to allow for compensatory growth of the remaining adrenal.[44,230,231] Labeling of cells with a single injection of BrdU, a synthetic nucleoside incorporated during DNA replication, followed by different periods of chase allowed demonstration of a continuous stream of BrdU+ cells from the outer to the inner cortex, associated with cell death as they reached the medulla.[232-236] Interestingly, whereas BrdU+ cells at the periphery did not express steroidogenic differentiation markers, BrdU+ cells within the cortex were differentiated.[236] Altogether, these experiments suggested that undifferentiated progenitor cells in the capsule and outer cortex could proliferate and migrate centripetally towards the medulla to reconstitute pools of differentiated cells throughout the cortex. This theory was demonstrated by lineage-tracing and genetic studies that have identified a number of stem and progenitor cell populations and the molecular pathways involved in their recruitment.[17,29,124]

Homeostatic Renewal

The first formal evidence for a pool of capsular stem and subcapsular progenitor cells came from analyses of the HH signaling pathway[17]

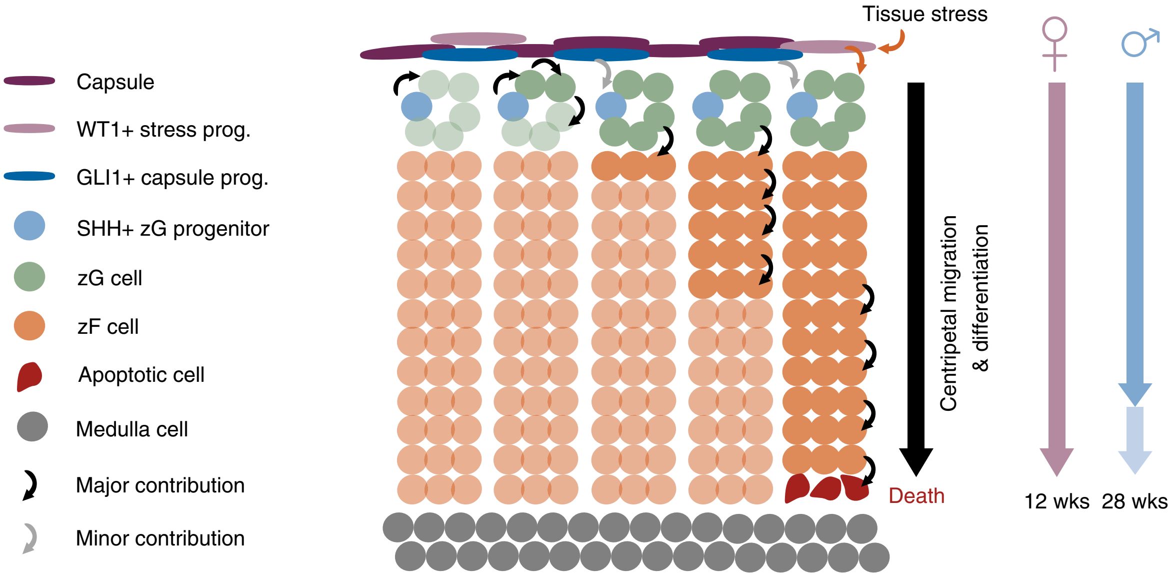

Fig. 85.8 Adrenal cortex renewal. Adrenal cortex homeostasis is maintained by constant renewal. This involves stem/progenitor cells located within the capsule and the zona glomerulosa (zG). Sonic hedgehog–positive (SHH+) zG cells ensure the majority of cortical renewal in the normal postpubertal adrenal cortex. After recruitment, SHH+ cells and their progeny initially differentiate as CYP11B2+ zG cells. They subsequently adopt a CYP11B1+ zF cell phenotype along their centripetal displacement within the cortex. When reaching the corticomedullary boundary, migrating cells enter apoptosis and are eliminated. GLI1+ cells can also contribute, albeit with low efficiency, to adrenal cortex renewal in both males and females before puberty. However, their contribution ceases in postpubertal males and is maintained in females. This sexual dimorphism is also reflected in the speed of renewal: full cortical replacement takes approximately 12 weeks in females and more than 7 months in males. WT1+ capsular cells are only mobilized following tissue stress, such as after gonadectomy. They may be mobilized in aging adrenals following the natural decline in sex steroids following menopause and andropause.

(see section on Sonic Hedgehog Signaling). The only HH ligand in the adrenal cortex is SHH, which is expressed in SF-1+ cells within zG rosettes.[17] Elegant lineage-tracing studies using *Shh-gfpCre* and *Shh-CreERT2* showed that SHH+ cells and their progeny migrate centripetally throughout the cortex. They differentiate as zG (CYP11B2+/SF-1+) cells and zF (CYP11B1+/SF-1+) cells. This showed that SHH+ cells are progenitors for both zG and zF[17] (Fig. 85.8). Lineage tracing also showed that SHH-responsive undifferentiated GLI1+/SF-1- capsular cells could also contribute to all steroidogenic lineages of the cortex and to a subset of SHH+ progenitors. However, their contribution to the different lineages is rather low during homeostasis and is sexually dimorphic[17,237] (see section on Sexual Dimorphism in Renewal). Early experimental evidence relying on trypan blue injections in the capsular and subcapsular space had shown that labeled cells could transit from the zG to the zF.[238] This, together with the observation that GLI1+ and SHH+ cells could contribute to both terminally differentiated lineages, suggested that cortical renewal occurs by sequential differentiation resulting from conversion of capsular cells to zG cells that subsequently adopt a zF phenotype during their centripetal displacement in the cortex. This was formally demonstrated by using the *Cyp11b2-Cre* driver and the mTmG reporter for lineage tracing. Indeed, whereas EGFP+ CYP11B2-derived cells were initially restricted to the zG (CYP11B2+/CYP11B1-), by 5 weeks, descendants of the CYP11B2 lineage were found in the zF (CYP11B1+/CYP11B2-). By 12 weeks in females, the entire zF was recombined, and all the cells in the zF had lost CYP11B2 expression and gained CYP11B1 expression.[124] Therefore, although it is technically challenging to prove that descendants of CYP11B2+ cells are also descendants of SHH+ and/or GLI1+ cells, these data demonstrate that the majority of adrenal cortex renewal occurs through sequential transdifferentiation from zG to zF, during migration within the cortex (Fig. 85.8). However, while this is the major homeostatic pathway, cells of the inner cortex can be derived independent of the CYP11B2 lineage under some extreme conditions.[124]

These findings raise the question of the mechanisms involved in transdifferentiation from zG to zF (Fig. 85.9). Analysis of models of constitutive activation of PKA throughout the cortex showed that this pathway plays an essential role in blocking Wnt pathway activation in adrenal steroidogenic cells, to allow conversion from a zG to zF phenotype. This inhibitory mechanism relies on inhibition of WNT4 expression and destabilization of β-catenin, through direct phosphorylation and indirect activation of GSK3β within the destruction complex.[85] Conversely, Wnt pathway activation was found to inhibit PKA signaling. Indeed, pharmacological activation of Wnt signaling in adrenocortical cells in culture resulted in repression of *MC2R* and *CYP11B1* expression.[239] This was further confirmed in mouse models of constitutive β-catenin activation in which expression of *CYP11B1* and AKR1B7 was inhibited[187,188] and conversion from fasciculata to glomerulosa was blocked, resulting in hyperaldosteronism.[186] This may involve overexpression of the phosphodiesterase PDE2A, a direct target of WNT/β-catenin signaling in the adrenal cortex,[186] but also inhibition of both SF-1 expression and transcriptional activity, presumably through titration and displacement of SF-1 from the promoters of steroidogenic genes, by β-catenin.[239]

Altogether, these findings strongly suggest that, after subcapsular SHH+ progenitor cells are recruited, they initially differentiate as zG cells under the influence of Wnt signaling, activated by WNT4 and further potentiated by RSPO3. This stimulates expression of AT1R and CYP11B2 and blocks expression of MC2R and CYP11B1. As cells migrate within the cortex, they progressively escape the positive

Fig. 85.9 Antagonistic interaction between WNT and PKA signaling pathways control zonal differentiation during renewal. After recruitment, sonic hedgehog–positive progenitor cells initially differentiate as zona glomerulosa cells under the influence of Wnt signaling, activated by WNT4 and further potentiated by RSPO3, which inactivates ZNRF3, allowing accumulation of Frizzled (FZD; Wnt receptor). This is reinforced by induction of WNT4 expression by β-catenin, which also stimulates expression of AT1R and CYP11B2 and blocks expression of MC2R and CYP11B1. Aldosterone is then produced under the control of Angiotensin II, acting through AT1R. As cells migrate within the cortex, they progressively escape the positive influence of RSPO3/WNT4. This prevents Wnt pathway activation by allowing ZNRF3-mediated clearance of FZD, resulting in a further decrease in WNT4 expression. This reduction in Wnt activation allows expression of MC2R, which in turn stimulates the PKA signaling pathway. This further inhibits expression of WNT4, prevents β-catenin accumulation, and stimulates expression of CYP11B1, allowing zona fasciculata differentiation and production of glucocorticoids.

influence of RSPO3/WNT4, which is further suppressed by ZNRF3-mediated downregulation of Wnt receptors.[185] This reduction in Wnt activation allows expression of MC2R, which in turn stimulates the PKA signaling pathway. This further inhibits expression of WNT4, prevents β-catenin accumulation, and stimulates expression of CYP11B1, allowing zF differentiation (Fig. 85.9).

Whether these mechanisms are also involved in the human adrenal cortex is unknown. However, consistent with mouse adrenals, proliferation in the human adrenal is also more concentrated in the outer cortex, whereas apoptosis is localized at the corticomedullary boundary.[240] There is also more intense staining for SHH at the periphery of the cortex and GLI1 expression in the capsule.[241,242] Interestingly, analysis of telomere length within the different zones of human adrenal cortices showed that telomeres were shorter in zF than in zG in subjects between 22 and 68 years of age, whereas they were identical in younger individuals.[243] This age- and zone-dependent telomeric attrition suggests that the human adrenal cortex also undergoes constant renewal, and that zF cells are older than zG cells, consistent with the sequential differentiation model. However, zR cells were found to have longer telomeres than either zG or zF.[243] This suggests that the zR may be established and/or maintained independently from the zG and zF.

Role of Renin-Angiotensin-Aldosterone System and Adrenocorticotropic Hormone/PKA Signaling in Regulation of Renewal

The RAAS and ACTH/PKA signaling pathways, which control endocrine activity and proliferation in the adrenal cortex, also play a role in progenitors' homeostasis. Indeed, in the context of genetic ablation of *Cyp11b2*, which results in a 5-fold increase in renin-angiotensin activation, lineage conversion from zG to zF is significantly accelerated, which is correlated with increased proliferation and expansion of the zG. This results in complete zF colonization by the descendants of zG cells after 5 weeks, compared with 12 weeks in wild-type mice.[124,186] This effect can be partially reversed by treatment with candesartan, indicating that cortical cell renewal can be stimulated by increased renin-angiotensin activity.[186] Interestingly, cortical cell renewal can also be accelerated by PKA signaling. Indeed, whereas 2-week treatment with dexamethasone to suppress pituitary ACTH secretion results in inhibition of zG-to-zF conversion,[124] constitutive activation of PKA using *Cyp11b2-Cre* is associated with a marked acceleration of cortical cell renewal.[128] Altogether, these data show that the major adrenal regulators of adrenal endocrine activity are able to stimulate adrenal cortex renewal to allow for sustained response to potentially chronic stimuli. How these hormones can stimulate differentiation, proliferation, and renewal remains unclear.

Sexual Dimorphism in Renewal

The adrenal cortex is a sexually dimorphic tissue. In mice, female adrenals are larger after puberty,[244-246] and sex-specific transcriptomic signatures have been described.[247,248] Interestingly, analysis of proliferation using BrdU injections showed that mature female adrenals had a much higher proliferation rate (6-fold) than male adrenals. This was partially compensated by a 2-fold increase in apoptosis at the corticomedullary junction, suggesting that female adrenals undergo a faster cell turnover than male adrenals.[237] Consistent with this hypothesis, lineage tracing using *Cyp11b2-Cre*, *Axin2-CreERT2,* or *Wnt4-CreERT2* showed full replacement of the adult female cortex by zG-derived cells after 3 months, whereas only 42% and 75% of cortical cells were derived from the zG after 3 and 7 months, respectively, in males (Fig. 85.8).[128,237] Lineage tracing using *Gli1-CreERT2* to identify the descendants of capsular progenitors at 3 weeks showed a similar contribution of these cells to differentiated cortical cells in males in females. However, when similar experiments were conducted after puberty, the contribution of GLI11+ cells to the differentiated cortex almost ceased in males, whereas it was maintained in females.[237] This shows that, whereas both prepubertal male and female adrenals use GLI11+ and SHH+ progenitors for cortical renewal, GLI11+ progenitors are only used in females after puberty. This suggests that male adrenals may be more sensitive to aging than female adrenals. Consistent with this idea, human aging male zF cells have shorter telomeres than age-matched female zF cells.[249]

How are these sexually dimorphic processes regulated? To evaluate a potential contribution of chromosomal sex, Grabek et al. used models of sex reversal consisting of XX males (overexpressing SOX9 under the control of *Wt1* regulatory regions) and XY females (bearing *Sf-1-Cre* mediated inactivation of SOX9). These experiments showed that XY females had increased capsular proliferation compared with control males, whereas XX males had decreased proliferation compared with control females. In contrast to control XX females, GLI1+ cells did not contribute to the pool of steroidogenic cells, which was reminiscent of XY males.[237] This suggested that sex-specific proliferation and recruitment were not dependent on sex chromosomes, but were rather controlled by sex hormones. Indeed, gonadectomy in male mice induced a significant increase in capsular proliferation and a 3-fold induction in recruitment of capsular cells to the steroidogenic lineage. Conversely, administration of the nonaromatizable androgen DHT to female mice inhibited proliferation and almost completely blocked GLI1+ progenitor recruitment.[237] Similar experiments using *Cyp11b2-Cre* to identify descendants of zG cells also showed that androgen deprivation in male mice could dramatically accelerate renewal, which was reversed by supplementation with DHT.[128] Altogether, these experiments show an all-encompassing role of androgens in inhibition of capsular progenitor cell recruitment and overall cortical cell renewal in male mice. Although the molecular mechanisms underlying this effect of androgens are not completely understood, transcriptomic analyses of castrated and supplemented mice suggest that they may involve stimulation of Wnt/β-catenin signaling, which would in turn counteract the prorenewal effects of PKA signaling.[128] These sexually dimorphic proliferation and renewal capacities may account for the female prevalence of adrenal diseases such as Cushing syndrome[250] and adrenocortical carcinomas.[251]

Adrenal Cortex Regeneration

Chronic administration of glucocorticoids is used for treatment of a number of medical conditions. By suppressing pituitary ACTH, these treatments result in adrenal cortex atrophy, which can be reversed by a regenerative process, following withdrawal of corticoids.[252,253] Recent experimental evidence in mice has shown that this process involves mobilization of adrenal progenitors in response to both HH and Wnt signaling pathways. Indeed, following chronic dexamethasone treatment removal, *SHH* expression is increased, and SHH+ and GLI1+ cells are mobilized to reconstitute a functional cortex.[204] This process can be efficiently blocked using GANT61, a specific inhibitor of GLI1 and GLI2 DNA-binding activity. Conversely, constitutive activation of HH signaling within GLI1+ cells using a SmoM2 mutant facilitates regeneration.[204] Wnt signaling is also actively engaged during adrenal cortex regeneration and inactivation of β-catenin in AXIN2+ Wnt-responsive cells inhibits the regeneration process.[204] This may involve direct stimulation of *SHH* expression by canonical Wnt signaling to trigger progenitor cell recruitment.[184,191,204] Failure of these processes may result in persistent adrenal insufficiency despite glucocorticoid withdrawal.[252,253]

Tissue Stress Progenitors and Adrenal Aging

Although SHH+ cells are the key progenitors for adrenal homeostasis, lineage-tracing studies have identified some other populations of cells that can be mobilized to respond to tissue stress. In the adult, lineage tracing with *Wt1-CreERT2* showed that WT1+ cells can give rise to fully differentiated steroidogenic cells, albeit at very low frequency (Fig. 85.8).[29] Interestingly, though, gonadectomy increases recruitment and differentiation of WT1-derived cells into the steroidogenic lineage, in both males and females. However, these cells are not fully differentiated and express features of gonadal steroidogenic cells, such as CYP17 and LHR, that are not found in normal adrenals.[29] Gonadectomy also induces subcapsular accumulation of GLI1-derived aberrantly differentiated steroidogenic cells that express the gonadal markers PDGFRα, FOXL2, and GATA4.[254] This gonadectomy-induced phenomenon is further amplified in the context of loss of adrenal inhibin (*Inha*-/-) and results in the development of adrenocortical tumors characterized by ovarian identity.[255] Further work has demonstrated that adrenal inhibin normally acts in an LH-dependent manner to oppose GATA4-mediated gonadal differentiation by antagonizing TGFβ2.[256] Interestingly, GLI1-derived subcapsular cells also accumulate in intact aging mice of the B6D2F2 strain,[254] which is reminiscent of the GATA4-positive subcapsular hyperplasia observed following gonadectomy or in intact aging mice.[67,257] On the basis of these observations, it is tempting to speculate that these GLI1/WT1-derived GATA4+ cells could accumulate in the adrenal, following the natural decline of sex steroids after menopause and andropause. Whether GLI1+, WT1+, and/or GATA4+ cells could contribute to suboptimal adrenal cortex renewal following late exhaustion of SHH+ progenitors remains to be investigated.

KEY POINTS

- Steroidogenic cells of the adrenal cortex are continuously renewed by the sexually dimorphic recruitment of stem and progenitor cells located in the capsule and within the zona glomerulosa (zG).
- Both GLI1+ capsular and sonic hedgehog–positive (SHH+) zG cells can contribute to cortex renewal in males and females before puberty, but GLI1+ contribution ceases in postpubertal males.
- SHH+ progenitors are the major source of steroidogenic cells during homeostasis in the adult.
- The vast majority of progenitor cells undergo sequential differentiation as zG cells and subsequent transdifferentiation into zone fasciculata cells during their centripetal migration within the cortex.
- Recruitment and sequential differentiation are tightly controlled by antagonistic interactions between Wnt/β-catenin and PKA signaling pathways.
- Progenitors are mobilized to allow adrenal regeneration following withdrawal from chronic glucocorticoid treatment.
- Some distinct Wilm's tumor suppressor-positive progenitors can be mobilized in response to abnormal tissue stress and may participate in renewal of the aging adrenal cortex.

CONCLUSION AND FUTURE DIRECTIONS

Since the first description of the adrenal gland by Bartholomeus Eustachius in 1563, significant progress has been made in understanding its role as a central regulator of the stress response, through secretion of corticoids and catecholamines. Over the last 25 years, a combination of human and mouse genetics has identified the key molecular mechanisms controlling the development, differentiation, and renewal of the adrenal cortex. This has translated into a better understanding of adrenal diseases ranging from insufficiency to aggressive tumor development. However, these novel findings have raised many questions that will need to be addressed to further our understanding of adrenal pathophysiology. Indeed, we still do not know how deregulation of adrenal cortex renewal, in particular in the aging gland, may play a role in development of adrenal diseases. In this respect, the appearance of abnormally differentiated subcapsular cell clusters such as aldosterone-producing cell clusters and DLK1+ clusters in the aging human adrenal is particularly intriguing.[258-261] Understanding the molecular underpinnings of the sexual dimorphism of adrenal cortex function and homeostasis will also undoubtedly shed light on the dimorphic nature of many adrenal conditions. Another key aspect that has been underestimated so far, is the multiple interactions between steroidogenic cells and their tissue microenvironment. The key role of such interactions has recently been illustrated by the demonstration of an important role of the neuropeptide substance P in controlling aldosterone secretion in human adrenals.[262] Answering these questions will help development of novel therapeutic approaches, such as regenerative therapies to treat adrenal insufficiency or targeted therapies to treat adrenocortical cancer patients.

Primary Adrenal Insufficiency: An Overview, 1430
Genetic Disorders of the Adrenal Cortex, 1431
Steroidogenesis, 1431
Hypoplasia, 1437
Familial Glucocorticoid Deficiency-Like (FGD-Like), 1439
Other Causes Of Syndromic Adrenal Insufficiency, 1441
Conclusion, 1443
Further Resources, 1443

KEY POINTS

- Primary adrenal insufficiency is a result of adrenal dysfunction and is characterized by low cortisol and aldosterone levels, as well as high adrenocorticotropic hormone.
- Conversely, secondary and tertiary adrenal insufficiency are results of disordered pituitary or hypothalamic function.
- Glucocorticoids, mineralocorticoids, and androgens are produced from cholesterol by enzyme cascades in the adrenal cortex.

PRIMARY ADRENAL INSUFFICIENCY: AN OVERVIEW

Primary adrenal insufficiency (PAI) is the result of disordered adrenal function and is characterized by low cortisol and aldosterone levels, as well as high plasma adrenocorticotropic hormone (ACTH). This differs from secondary and tertiary adrenal insufficiency (SAI), resulting from disordered pituitary or hypothalamic function, which presents with low cortisol levels and ACTH deficiency. While cortisol and aldosterone are both deficient in PAI, in SAI, where the adrenals remain functional, it is only cortisol levels that are reduced. This is due to aldosterone being regulated through the renin-angiotensin system (RAS) and explains the relatively different clinical presentation of PAI and SAI.

Glucocorticoid production is discussed in detail elsewhere in this text, but in brief, ACTH, produced in the pituitary gland under the control of the hypothalamus–pituitary–adrenal axis, induces cortisol production through both transcription-independent stimulation and increased gene expression of steroidogenic enzymes via melanocortin 2 (MC2R) receptors in the adrenocortical cells of the zona fasciculata.[1] Upon ACTH activation, cholesterol is transported to the inner mitochondrial membrane (IMM) by steroidogenic acute regulatory protein (STAR) and converted to pregnenolone by cytochrome P450 side chain cleavage enzyme (CYP11A1) (Fig. 86.1). Pregnenolone is subsequently transported out of the mitochondria and hydroxylated to 17-OH-pregnenolone by P450c17 (CYP17A1) before being converted to 17-OH-progesterone (17-OHP) through the action of 3β-hydroxysteroid dehydrogenase (HSD3B2) at the endoplasmic reticulum. 17-OHP is next hydroxylated by P450c21 (CYP21A2) to produce 11-deoxycortisol, which is then returned to the mitochondria, and P450c11β (CYP11B1) completes the cortisol synthesis pathway.[2] Glucocorticoids regulate ACTH secretion by a negative feedback loop,[3,4] maintain cardiac function,[5-7] and are essential for hepatic glycogen deposition.[4,8] Consequently, glucocorticoid deficiency typically presents with hypoglycemia, hypotension, reduced stroke volume, and ACTH-mediated hyperpigmentation (via activation of MC1R in melanocytes).

Aldosterone production takes place in the zona glomerulosa, the outermost layer of the adrenal cortex, where its synthesis is controlled by the RAS. Briefly, a drop in blood pressure results in the release of renin from juxtaglomerular cells in the kidneys, which is then proteolytically cleaved by angiotensinogen from the liver to produce angiotensin I. Angiotensin-converting enzyme produced by the lungs converts angiotensin I to angiotensin II, which stimulates the release of aldosterone from the adrenal cortex via binding to angiotensin II receptor type I.[9] Upon angiotensin II activation, cholesterol is processed in the same manner as cortisol synthesis to produce pregnenolone. With the absence of P450c17 in the zona glomerulosa, pregnenolone is solely converted to progesterone through HSDB2. Progesterone is subsequently oxidised by P450c21 to 11-deoxycorticosterone (DOC), substrate for zona glomerulosa-specific P450c11AS (CYP11B2), which produces corticosterone, a glucocorticoid. Corticosterone is then further processed through the action of P450c11AS to produce 18-hydroxycorticosterone and finally aldosterone.[2] Mineralocorticoids regulate sodium, potassium and hydrogen ion levels in the kidneys, and therefore a deficiency of these can result in hypotension, hyponatremia, hyperkalemia, and metabolic acidosis.[10]

The functions of corticosteroids and the effects of their absence due to autoimmune and infectious adrenal insufficiency are explored extensively elsewhere in the text. This chapter will provide an overview of the clinical phenotype, comorbidities, and mechanisms of action (where known) for genetic disorders of the adrenal cortex resulting in PAI.

KEY POINTS

- Primary adrenal insufficiency can be caused by hereditary mutations that affect steroidogenic enzymes, development and growth of the adrenal gland, resistance to adrenocorticotropic hormone action or adrenal destruction.

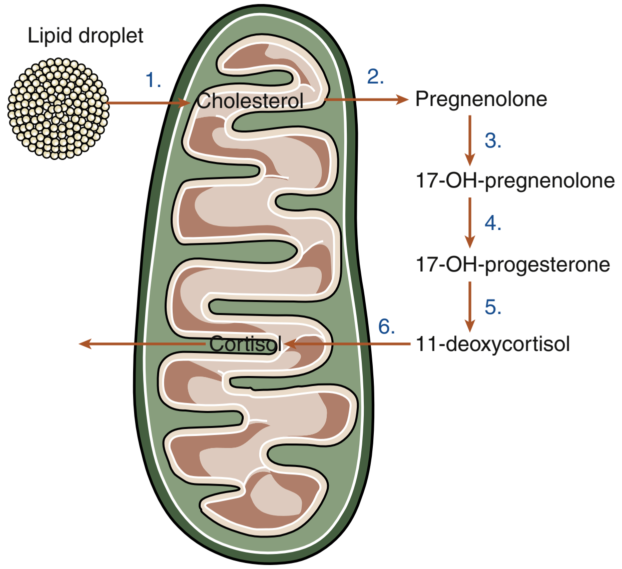

Figure 86.1 **Cortisol production pathway in the zona fasciculata.** CYP11A1 conversion of cholesterol to pregnenolone is the rate-limiting step of steroidogenesis, performed at the inner mitochondrial membrane. Pregnenolone is transported to the endoplasmic reticulum, where a cascade of enzyme activity results in the production of 11-deoxycortisol, which is subsequently returned to the mitochondria and converted to cortisol. The genes encoding the enzymes involved at each step of the pathway are as follows: 1. *STAR*, 2. *CYP11A1*, 3. *CYP17A1*, 4. *HSD3B2*, 5. *CYP21A2* 6. *CYP11B1*.

GENETIC DISORDERS OF THE ADRENAL CORTEX

PAI encompasses a heterogeneous group of diseases distinguished by decreased production of cortisol and steroid hormones by the adrenal cortex and arises from anomalies in the development of the adrenal gland, impaired steroidogenesis, resistance to ACTH action (familial glucocorticoid deficiency [FGD]) or adrenal destruction. In adults, most cases are caused by adrenal destruction due to autoimmune Addison disease, whereas in childhood the cause is usually hereditary and monogenic in origin and may be related to considerable morbidity and mortality. The International Classification of Pediatric Endocrine Diagnoses Consortium (http://www.icped.org/) classifies them into congenital adrenal hyperplasias (CAH), adrenal hypoplasia congenita (AHC), and FGD-like (http://www.icped.org/revisions/0/2015/diagnoses/#!/8), with CAH and AHC leading to adrenal insufficiencies of both gluco- and mineralocorticoids, whereas in FGD-like disease patients chiefly lack glucocorticoids (Table 86.1).

CAH accounts for most of PAI cases in childhood, with the most common type due to mutations in *CYP21A2*, but defects in *CYP11B1*, *CYP17A1*, *CYP11A1*, and *HSD3B2* can also result in CAH.[11] This results in a compensatory increase in ACTH that drives the adrenal hyperplastic response due to its trophic action on adrenocortical cells.[12,13] Congenital adrenal hypoplasia is characterized by underdevelopment of the adrenal glands and can be caused by defects in nuclear receptor subfamily 5, group A, member 1 (NR5A1) or the nuclear receptor subfamily 0, group B, member 1 (NR0B1) but is also seen as a constituent part of complex multisystem growth disorders caused by mutations in genes such as cyclin-dependent kinase inhibitor 1C (*CDKN1C*) (Table 86.1).

Finally, FGD-like or ACTH resistance syndromes[14] are characterized by isolated glucocorticoid deficiency in a patient who retains normal mineralocorticoid production. FGD-like syndromes have considerable phenotypic variation, dependent on the gene defect, but normally present at an early age with neonatal hypoglycemia, seizures, hyperpigmentation, and increased susceptibility to infection. The first mutations were identified in MC2R and its accessory protein MRAP; however, with advances in next-generation sequencing and genetic diagnosis tools, further gene mutations have been discovered that give rise to disorders with isolated cortisol deficiency through defects in cell proliferation (mini-chromosome maintenance complex component 4 [*MCM4*]) and cellular redox balance (nicotinamide nucleotide transhydrogenase [*NNT*] and thioredoxin reductase 2 [*TXNRD2*]).

KEY POINTS

- Mutations in genes that encode adrenal steroidogenic enzymes are common causes of congenital adrenal hyperplasia.
- Congenital adrenal hyperplasia can present differently depending on the dysfunctional enzyme, and patients can have varied glucocorticoid, mineralocorticoid, and androgen production.
- Mutations in *CYP11A1* and *STAR* can also cause congenital lipoid adrenal hyperplasia, a disease where lack of hormone production results in increased accumulation of cholesterol, and consequently mitochondrial oxidative damage.

Steroidogenesis

Defects in enzymes within the adrenal steroidogenic cascade (Fig. 86.2) are common causes of CAH. As a complex network of enzymes, mutations in different genes can cause variable disease phenotypes due to deficiency of glucocorticoid, mineralocorticoid, or both, as well as possible gonadal insufficiency.

Cytochrome P450 Family 21 Subfamily A Member 2 (*CYP21A2*). *CYP21A2* encodes steroid 21-hydroxylase, the steroidogenic enzyme that converts progesterone to deoxycortisone and 17-OHP to deoxycortisol (Fig. 86.2). Mutations in *CYP21A2* cause 90% of CAH and result in reduced mineralocorticoid and glucocorticoid production, as well as androgen excess, leading to hypergonadism. CAH due to steroid 21-hydroxylase deficiency presents with three major phenotypes: classical salt-wasting, classical simple virilizing, and nonclassical. The absence of aldosterone results in the inability to retain sodium, which is consequently lost in urine, a process known as salt wasting.[15] Classical salt-wasting is the more severe of the two classical forms and constitutes 75% of cases.[16] Due to mutations resulting in less than 2% enzyme activity, undiagnosed cases can lead to life-threatening adrenal crisis in the first 2 weeks of life.[17,18] In addition, 46, XY patients are born with normal genitalia, putting them most at risk, while 46, XX patients are commonly born with genital ambiguity, prompting further evaluation and treatment.[18] For classical salt-wasting cases, both mineralocorticoid and glucocorticoid therapy are required. In the simple virilizing cases, which possess greater than 2% enzyme activity, sufficient aldosterone is produced to prevent salt wasting. For both disease variants, patients undergoing postnatal development may develop signs of androgen excess, including precocious pubarche, adrenarche, acne, and advanced bone age leading to reduced final height.[19,20] Furthermore, 46, XY patients are likely to develop testicular adrenal rest tumors, benign testicular tumors that morphologically and functionally resemble adrenal tissue.[21] Patients with the nonclassical form of the disease retain up to 50% of enzyme activity. This allows sufficient hormone production to prevent adrenal insufficiency and genital ambiguity in 46, XX patients, resulting in many patients going undiagnosed.[18,22] The primary method to diagnose steroid 21-hydroxylase deficiency is to measure serum levels of 17-OHP, the substrate for steroid 21-hydroxylase, during newborn screening.[18]

IMPC, International Mouse Phenotyping Consortium; *ER*, endoplasmic reticulum; *CLAH*, congenital lipoid adrenal hyperplasia; *AR*, autosomal recessive; *AD*, autosomal dominant; *XR*, X-linked recessive; *OMIM*, online Mendelian inheritance in man.

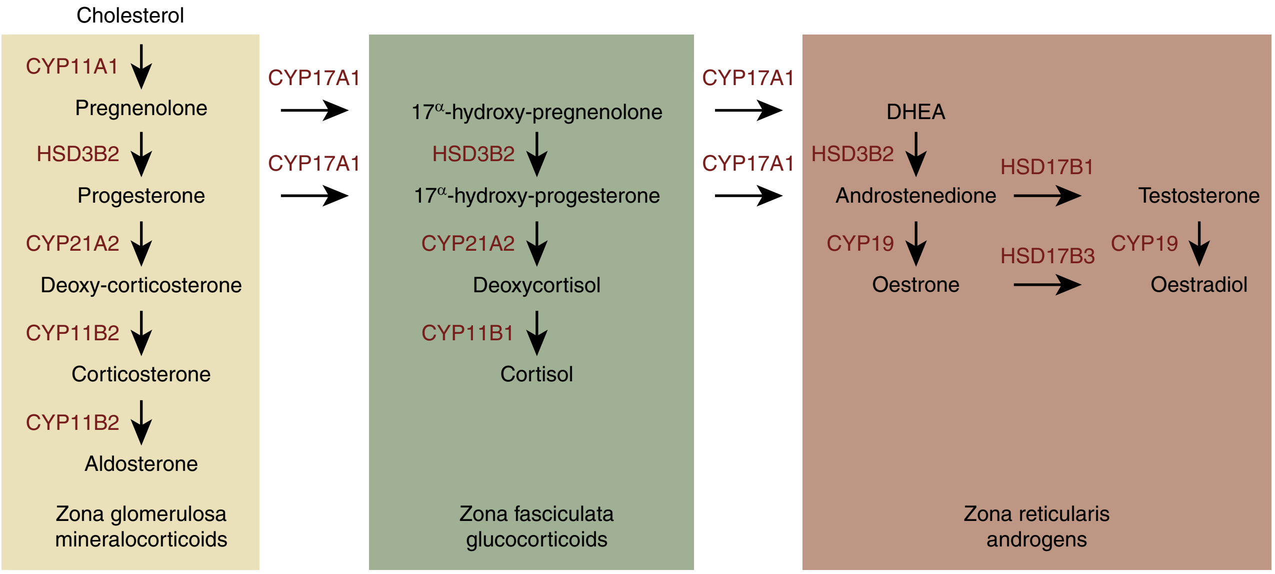

Figure 86.2 **Steroidogenic cascade of the adrenal gland.** The adrenal gland produces mineralocorticoids, glucocorticoids, and androgens in different zones of the cortex. Mutations in several of the *CYP* genes result in congenital adrenal hyperplasia, leading to a compensatory increase in adrenocorticotropic hormone that drives the adrenal hyperplastic response due to its trophic action on adrenocortical cells. *DHEA,* dehydroepiandrosterone.

A naturally occurring mouse strain, H-2aw18, with deletion of *cyp21* and complement component c4 due to meiotic recombination, dies at an early postnatal stage.[23] The loss of *cyp21* leads to hyperproduction of ACTH with adrenocortical hyperplasia and accumulation of precursor steroids.[24] Because mouse adrenals lack steroid 17-alpha-hydroxylase/17,20 lyase, the accumulated precursor is progesterone, and no androgenization occurs. The adrenals of these mice present with lack of zonation, hypertrophy, and hyperplasia of adrenocortical mitochondria, although adenovirus-mediated transfer of human steroid 21-hyrdoxylase into these mice has been shown to transiently restore adrenal steroidogenesis.[24]

Steroidogenic Acute Regulatory Protein (*STAR*). STAR is part of a complex responsible for the transportation of cholesterol from the outer mitochondrial membrane to the IMM, where it is processed to pregnenolone, reported as the rate-limiting step of steroidogenesis (Fig. 86.1). Along with mitochondrial cholesterol side-chain cleavage enzyme (CYP11A1), it is one of the key factors in hormone production in both the adrenals and the gonads.[25] Mutations in *STAR* therefore inhibit the delivery of cholesterol to the steroidogenic enzyme cascade and prevent glucocorticoid and mineralocorticoid production.[26] This shutdown of steroidogenesis due to mutations in *STAR* is known as congenital lipoid adrenal hyperplasia (CLAH), first characterized in 1996.[27] Patients with this condition present in the first month of life with salt-wasting adrenal and gonadal insufficiency.[28] Due to dysfunctional gonadal steroidogenesis, CLAH infants with a 46, XY karyotype fail to produce testosterone *in utero* and have female genitalia, while infants with a 46, XX karyotype present with variable ovarian insufficiency at adolescence.

A two-hit model has been proposed to account for the pathogenesis of CLAH, with the first "hit" being lack of *STAR* and the second being cholesterol-mediated oxidative damage.[27] Upon ACTH stimulation, a steroidogenic cell gathers cholesterol from endogenous synthesis, stored lipid droplets or low-density lipoprotein (LDL) receptor-mediated endocytosis, and STAR subsequently facilitates transport through the mitochondria. In cells with defective STAR transport, only minimal residual STAR-independent steroid biosynthesis occurs, resulting in low levels of steroidogenesis (first hit). Inadequate steroid levels drive an increase in steroidogenic stimuli and culminate in the accumulation of cholesterol within the cells. This progressive lipid accumulation leads to mitochondrial oxidative damage, which eventually culminates in reduced steroidogenic capacity and enlarged adrenal size (second hit).[27]

Beyond the "classic" disease of CLAH, partial defects in *STAR* can cause nonclassic CLAH (NCLAH) in 5% to 10% of patients.[29,30] This disease predominantly affects glucocorticoid synthesis and masquerades as FGD, as patients have normal genitalia and may be fertile. Variants pR188C and pR192C reduce STAR's interactions with the 3–βOH group of cholesterol and cause partial loss of function (LOF).[29,30] Long-term reproductive follow-up is required for NCLAH patients to ensure that correct pubertal development occurs, and appropriate counseling and sperm banking may be offered.[28]

Star knockout mice are born normally, indicating that STAR is not required for survival *in utero*; however, both genetic male and genetic female mice have female external genitalia.[31] Most mice die within 1 to 2 days of birth, with none surviving beyond 16 days without treatment, most likely due to respiratory distress secondary to adrenal insufficiency.[31] This was supported by the survival of pups that underwent corticosteroid replacement. Furthermore, levels of corticosterone and aldosterone were low compared to littermates, while levels of ACTH were elevated. Finally, although adrenal glands were smaller in knockout mice, they showed high quantities of lipid deposition, supporting the second hit of the two-hit model of CLAH.[31]

Cytochrome P450, Family 11, Subfamily A Member 1 (*CYP11A1*). *CYP11A1* encodes the mitochondrial cholesterol side-chain cleavage enzyme that performs the rate-limiting step of steroidogenesis, cholesterol conversion to pregnenolone, at the beginning of the steroidogenic enzyme cascade (Fig. 86.2). Pregnenolone is subsequently processed to produce cortisol, aldosterone, and androgens in different pathways and, consequently, loss-of-function mutations can cause CAH associated with glucocorticoid and mineralocorticoid deficiency, as well as disorders of sex development. Absence of the enzyme was previously believed to be incompatible with term gestation; however, several patients with side-chain cleavage enzyme deficiency have been reported, initially in 2001.[32-34]

Mutations in *CYP11A1* classically result in mitochondrial cholesterol side-chain cleavage enzyme syndrome characterized by primary adrenal failure in combination with 46, XY sex reversal, although, unlike STAR-deficient subjects, adrenal size is unaffected. Similar to *STAR,* partial loss-of-function mutations (retention of up to 20% of wild-type function) can produce a nonclassic form of the disease with a phenotype of predominant glucocorticoid deficiency with variable degrees of mineralocorticoid deficiency and sexual development, depending on the residual activity of the mutant proteins.[35-38] Patients can present at different ages during infancy, typically with hyperpigmentation, hypoglycemia, or prolonged illness with infections.[28]

Two recent studies have found that missplicing of *CYP11A1* mRNA results in a truncated version of the protein that can cause adrenal insufficiency.[39,40] Genetic analysis revealed that many families of European heritage with PAI are compound heterozygous for a c.940G>A variant (rs6161) on one allele of *CYP11A1,* with a second disruptive change on the other allele.[39] The *in vitro* splicing assays showed that the predicted benign change of c.940G>A (p.E314K) resulted in missplicing and a truncated protein consistent with cleavage at the predicted amino acid change.[39,40] This variant is carried by 1:140 people of European descent but has only been shown to cause PAI when inherited with a rare disruptive change on the other allele.[28]

A study investigating *Cyp11a1* null mice showed that they do not survive weaning and present with corticosterone and aldosterone deficiency compared with wild-type littermates. However, when treated with corticosteroids they survive to adulthood. *Cyp11a1*$^{-/-}$ XY males exhibit sex reversal with feminization of external genitalia and disorganization of internal genitalia. The adrenals of the null mice are reduced in size, although they do show progressive lipid accumulation similar to *Star* knockout mice.[41]

Hydroxy-Delta-5-Steroid Dehydrogenase, 3 Beta- And Steroid Delta-Isomerase 2 (*HSD3B2*). Mutations in *HSD3B2* result in a very rare variant of CAH causing less than 0.5% of cases.[42] HSD3B2 catalyzes the conversion of Δ5-3β-hydroxysteroids (pregnenolone, 17-hydroxypregnenolone and dehydroepiandrosterone [DHEA]) to Δ4-3-ketosteroids (progesterone, 17-OHP and androstenedione) (Fig. 86.2). HSD3B2 deficiency therefore impairs the synthesis of aldosterone, cortisol, and testosterone and results in high levels of renin, ACTH, and DHEA.[43] DHEA can be converted to androstenedione by extraadrenal HSD3B1, resulting in high levels of testosterone in females, although this fails to compensate for absence of the hormone in males.[43,44]

Severe impairment of steroid synthesis was first mapped to *HSD3B2* through identification of nonsense and frameshift mutations in 1992.[45] In general, frameshift and nonsense mutations present with a salt-wasting phenotype, while missense mutations are associated with residual enzyme activity and a non-salt-wasting phenotype.[15,46] Further presenting symptoms include incomplete masculinization in 46, XY patients, virilization in 46, XX patients, gynecomastia in males, hypospadias, and palpable testis.[47-49] This form of CAH is best diagnosed by high levels of 17-hydroxypregnenolone in the blood plasma and is treated with glucocorticoid, mineralocorticoid, and possibly sex hormone replacement therapy.

Cytochrome P450 Family 17, Subfamily A, Polypeptide 1 (*CYP17A1*). Due to its location in the steroidogenic cascade (Fig. 86.2), steroid 17-alpha-hydroxylase/17,20 lyase (CYP17A1) acts as the exclusive gateway to androgen production, with severe mutations resulting in impaired adrenal and gonadal sex steroid production, causing sexual infantilism and pubertal failure.[44,50] Steroid 17-alpha-hydroxylase/17,20 lyase functions in the conversion of pregnenolone to 17-hydroxypregnenolone and onwards to DHEA, as well as that of progesterone to 17-OHP and onwards to androstenedione, and therefore deficiency of the enzyme results in low cortisol and androgens but high levels of DOC and corticosterone (Fig. 86.2). Pubertal failure is therefore a prominent feature of steroid 17-alpha-hydroxylase/17,20 lyase deficiency. Importantly, however, due to the high levels of DOC and corticosterone, which possess glucocorticoid properties, mutations in *CYP17A1* do not result in glucocorticoid deficiency and adrenal crisis.[44] High levels of DOC, however, cause sodium retention, leading to hypertension and consequently suppression of aldosterone production.

CYP17A1 deficiency was first identified in 1988 in a patient with a four-base duplication.[51] 46, XY patients with *CYP17A1* mutations are usually diagnosed at birth due to ambiguous external genitalia.[52] Conversely, as patients do not undergo adrenal crisis at a young age, many 46, XX patients are not diagnosed until adolescence. Although DOC accumulates, manifestations of mineralocorticoid excess tend not to occur until adolescence, where it presents with hypertension and hypokalemia.[50] At puberty, lack of DHEA prevents adrenarche and development of pubic and axillary hair, and 46, XX patients can present with amenorrhea without hypertension and ovarian cysts.[53-55] At present there are no published examples of successful pregnancy in which either partner has 17-hydroxylase deficiency. The deficiency is treated with the appropriate androgen replacement therapy and partial glucocorticoid replacement. While glucocorticoid therapy is not essential, due to corticosterone substitution, it functions to prevent adrenal axis suppression and normalize blood pressure, and therefore a partial replacement is used as a compromise.[50] In one study, *Cyp17a1*$^{-/-}$ mice died around embryonic day 7 and could not be rescued through maternal administration of DHEA, androstenedione, and 17-OH pregnenolone.[56] The International Mouse Phenotyping Consortium, however, presents data indicating that mice reach adulthood but display varying phenotypes, including increased circulating cholesterol level and absent male genitalia.

Cytochrome P450 Oxidoreductase (*POR*). Cytochrome P450 oxidoreductase (POR) is a flavoprotein that plays a key role in electron transport, donating electrons to mitochondrial P450 enzymes including steroid 17-alpha-hydroxylase/17,20 lyase and steroid 21-hydroxylase and aromatase (CYP19A1).[44] Therefore, in POR deficiency (PORD), a reduction in steroidogenesis is due to impairment of key steroidogenic enzymes resulting in a lack of glucocorticoids and androgens. As POR acts an electron donor for all microsomal cytochrome P450 enzymes, there are multiple comorbidities associated with PORD. These can, but do not always, include changes in drug metabolism, pathogenesis of skeletal dysplasia, and other skeletal manifestations that resemble Antley–Bixler syndrome.[57-59]

The first mutations in POR linked with disordered steroidogenesis were identified in 2004.[59] Most POR mutations retain some enzymatic function, resulting in high levels of pregnenolone, progesterone, 17-OHP, DOC, and corticosterone, low levels of DHEA and androstenedione, and variable levels of cortisol and aldosterone.[44,60] Affected individuals can be detected *in utero,* as fetoplacental deficiency of POR can lead to virilization of the mother due to defective conversion of androgen precursors to estrogen.[59] Once born, affected 46, XX patients present with ambiguous genitalia, but circulating androgens remain at a low level, and virilization does not progress.[61] Urinary steroid metabolite profiling also provides a further useful noninvasive method for diagnosis.[44] PORD presentation varies greatly, from amenorrhea and polycystic ovaries in 46, XX patients and androgen deficiency in 46, XY patients to severe hormone disturbances resulting in atypical genitalia. One study showed that more than 80% of 46, XX patients in their cohort presented with differences in sex development (DSD), whereas DSD was present in only half of 46, XY patients.[62] Patients do not develop mineralocorticoid deficiency, but require permanent or stress-dosed glucocorticoid replacement therapy.

In one study, targeted deletion of the translation start site and membrane-binding domain in *Por*$^{-/-}$ mice resulted in embryonic lethality by day 13.5 of gestation, with embryos possessing multiple defects including abnormalities in the neural tube, heart, eye, and limb or a gross retardation of development.[63] A further study created a hypomorphic mouse with 5% to 26% of normal POR activity that grew to adulthood and presented with decreased weight and decreased heart, lung, and kidney size.[64] Interestingly no adrenal phenotype was noted in these mice.

KEY POINTS

- Mutations in certain genes can cause congenital adrenal hypoplasia, which is underdevelopment or hypotrophy of the adrenal cortex.
- Mutations in the genes encoding the transcription factors NROB1 and NR5A1 affect the transcription of genes involved in steroidogenesis and the development of the adrenal glands themselves.
- Mutations in genes such as *CDKN1C*, *SAMD9,* and *POLE1* can cause complex multisystem growth disorders that contain adrenal hypoplasia as a hallmark of the disease.

Hypoplasia

Adrenal hypoplasia is the underdevelopment or hypotrophy of the adrenal cortex leading to reduced steroid hormone production, and subsequently PAI. For more detail on adrenocortical developmental genetics, refer to Chapter 85.

Nuclear Receptor Subfamily 0 Group B Member 1 (*NROB1*). AHC is a condition that results from the underdevelopment of the adrenal gland. It is caused by LOF mutations to dosage-sensitive sex reversal, adrenal hypoplasia critical region on chromosome X, DAX1, encoded by *NROB1*, and classically presents with PAI and associated salt-wasting, hypogonadotropic hypogonadism (HH), and infertility.[28] DAX1, a transcription factor belonging to the nuclear receptor superfamily, acts as a transcriptional repressor of genes involved in the steroidogenic pathway and the development of the hypothalamus–pituitary–gonadal axis.[65,66] DAX1, in part, serves as a transcriptional repressor of steroidogenic factor 1 (SF-1, also known as NR5A1)-mediated transcriptional activation. Furthermore, DAX1 downregulates anti-Müllerian hormone (AMH), a hormone that, in 46, XY embryos, inhibits folliculogenesis and development of female gonads.[67] Loss of DAX1-dependent inhibition therefore results in abnormal gonad development in 46, XY patients. This is supported by DAX1-deficient mice presenting with testicular abnormality and infertility.[68]

Pathogenic variants in *NROB1* were first reported as a cause of X-linked AHC in 1994.[69] Its association with Duchenne muscular dystrophy and glycerol kinase deficiency allowed for an AHC-critical region of 200 to 500 kb to be physically mapped to the short arm of the X chromosome.[69] Most affected infants present within the first months of life with classic PAI symptoms: low cortisol, high ACTH, low aldosterone, and increased renin resulting in salt wasting.[70] Affected individuals are therefore treated with replacement doses of hydrocortisone and salt supplements, as well as sex hormone replacement to induce puberty if necessary. Patients may also present with paradoxical features such as precocious puberty, making the clinical spectrum of the disease quite variable.[71] Late-onset X-linked AHC has also been well documented. Patients can also present with partial HH and infertility. This is often due to a partial LOF variant in the ligand-like binding domain or an early stop variant leading to translation of a truncated protein.[72-74] Moreover, late-onset adrenal failure in patients with AHC has been preceded by cortisol excess in some patients.[75] While it remains unclear how LOF *NROB1* mutations could lead to these disparate adrenal phenotypes,[65,66] data in mice with genetic LOF mutations in *NROB1* are consistent with premature adrenocortical progenitor cell differentiation at the expense of ultimate adrenal failure.[76]

Nuclear Receptor Subfamily 5 Group A Member 1 (*NR5A1*). SF-1 is a transcription factor belonging to the nuclear receptor superfamily and acts as a master regulator of both adrenal and gonadal development.[77] Expressed in the adrenal cortex, testicular Leydig cells, and ovarian theca cells, SF-1 regulates the transcription of genes encoding key steroidogenic enzymes such as CYP11A1, CYP11B1, CYP21, and STAR, as well as AMH, gonadotrophins, and aromatase.[78] Indeed, SF-1 acts as an active determinant of gender differentiation through upregulation of *AMH.*[79] As demonstrated in mice, loss of Sf-1 can therefore cause adrenal agenesis, gonadal dysgenesis with a subsequent female phenotype, and variable degrees of HH.[78]

Mutations in *NR5A1* were first associated with adrenal insufficiency and XY sex reversal in 1999.[80] Here a 46, XY patient presented with primary adrenal failure as well as phenotypically female genitalia as a result of failure of Müllerian regression due to loss of SF-1–directed AMH production. In 46, XY patients, pathogenic variants are associated with a range of phenotypes, including testicular dysgenesis/dysfunction, severe hypospadias, and infertility.[81] Primarily causing defects in reproductive development, *NR5A1* mutations have rarely been associated with PAI, with only six patients documented to date.[28] Affected individuals with PAI can present with hyperpigmentation, hypotonia, jaundice, weight loss, and failure to thrive.[82]

Wnt Family Member 4 (*WNT4*). WNT4 belongs to the large WNT family of secreted glycoproteins that play a key role in the development of multicellular animals. WNT4 itself is considered the most important molecule for the correct differentiation of female gonadal tissues and is also known to play a role in the development of the kidneys, adrenals, pituitary gland, and mammary tissues.[83,84] Considering that the gonads, kidneys, and adrenals all originate from the urogenital ridge, it can be assumed that WNT4 functions in early embryological development. Mutations in *WNT4* can therefore disrupt the normal development of these organs and cause adrenal insufficiency. WNT4 is also known to repress the steroidogenic enzymes *CYP17A1* and *HSD3B2,* and consequently loss of WNT4 leads to androgen excess and sex reversal.[85]

Adrenal insufficiency due to *WNT4* mutations is rare, and the autosomal recessive syndrome it causes, SEx Reversion, Kidneys, Adrenal and Lung dysgenesis (SERKAL) syndrome, has been identified in three fetuses.[86] This study used a candidate gene approach to identify a homozygous missense mutation in *WNT4* (p.A114V) in three terminated fetuses. The parents of two of these fetuses were second-degree cousins, with the third fetus also belonging to the wider kindred, and the pregnancies were terminated due to renal agenesis determined through ultrasonic scanning. This mutation markedly reduced *WNT4* mRNA levels in transfected ovarian epithelium cells compared with wild-type *WNT4*, resulting in a downregulation of WNT4-dependent inhibition of β-catenin degradation.[86] This change in β-catenin-induced gene expression could result in the developmental defects witnessed in SERKAL syndrome. *Wnt4*-deficient mice die within 24 h of birth, showing signs of kidney dysfunction and improper development of the pituitary gland, as well as partial sex reversal in females.[87-89] In the adrenal cortex, *Wnt4*-deficient mice showed reduced expression of Cyp11b2 in the zona glomerulosa, resulting in significantly lowered aldosterone secretion in newborn mice, suggesting a role of Wnt4 in the development and maintenance of the zona glomerulosa.[90] A mouse model in which Wnt4 was depleted in the adrenal cortex corroborated these results, while also uncovering crucial crosstalk between PKA and Wnt-beta catenin signaling in determining the differentiation and fate of zona glomerulosa cells.[91]

Cyclin Dependent Kinase Inhibitor 1c (*CDKN1C*). A complex multisystem growth disorder that involves PAI is IMAGe syndrome, characterized by Intrauterine growth restriction, Metaphysical dysplasia, Adrenal hypoplasia, and Genitourinary anomalies (in males), and was first described in 1999.[92] The syndrome is normally caused by heterozygous missense variants in cyclin-dependent kinase inhibitor 1C (CDKN1C), a negative regulator of cell proliferation. All identified mutations that cause IMAGe syndrome are clustered in the proliferating cell nuclear antigen (PCNA) binding domain and cause a gain-of-function resulting in repressed growth.[93] The mechanism is still unclear but may involve reduced degradation of CDKN1C and subsequently prolonged cell cycle repression by impairing entry into S phase.[28,94] Conversely, LOF mutations outside of the PCNA binding domain of the *CDKN1C* gene contribute to the overgrowth phenotype of Beckwith–Wiedemann syndrome (including adrenal cytomegaly) due to an imprinting defect of the *IGF2* locus at 11p15 (containing *CDKN1C*).[93]

IMAGe syndrome is clinically variable, with some patients presenting without adrenal insufficiency and with diabetes mellitus.[95] This diabetes phenotype is most likely due to CDKN1C being involved in insulin-producing β cells. *CDKN1C* is paternally imprinted on chromosome 11 and is consequently only expressed from the maternal allele; while this inheritance can mimic an X-linked disease, IMAGe syndrome patients can be male or female.[96] Expression of IMAGe-causing mutations (mutations in the PCNA binding domain) in a human embryonic kidney (HEK) cell line demonstrated that, in IMAGe syndrome CDKN1C becomes more stable and does not undergo normal cell cycle–related oscillation, inhibiting progression from the G1 phase.[94] Overexpression of wild-type CDKN1C and Beckwith–Wiedemann syndrome mutant CDKN1C both inhibited cell proliferation, but not to the same extent as the IMAGe mutant. No mouse line has been created with an IMAGe-mutant *CDKN1C,* but a mouse containing a Beckwith–Wiedemann mutant *CDKN1C* presented with no adrenal phenotype.[97]

Sterile Alpha Motif Domain Containing 9 (*SAMD9*). A further complex multisystem growth restriction disorder that causes adrenal hypoplasia is MIRAGE syndrome, named according to it symptoms: Myelodysplasia, Infections, Restricted growth, Adrenal hypoplasia, Gonadal anomalies, and Enteropathy.[98] The syndrome is a result of gain-of-function mutations in the growth suppressor gene *SAMD9,* located on the long arm of chromosome 7 (7q21.2).[98,99] Conversely, LOF mutations have been reported in tumors, including normophosphatemic familial tumoral calcinosis.[100] Patients with MIRAGE syndrome commonly die at a young age (<2 years) due to invasive infection, are born preterm, and have variable intellectual development, and patients who do survive show limited pubertal progression.[28,98] They can also present with further symptoms, including respiratory distress, anemia, and thrombocytopenia.[28]

SAMD9 was first discovered to cause MIRAGE syndrome by a study performed in Japan that involved whole-exome sequencing of six patients presenting with adrenal hypoplasia but no mutations in other known genes.[98] Three patients were found to have variants in *SAMD9,* and subsequent Sanger sequencing of other cohort members identified a further eight patients, with eight different variants in total, almost exclusively *de novo*.[98] Postmortem analysis of two 46, XX patients who died before 2 years of age showed very small and disorganized adrenal glands, with the medulla only partially surrounded by cortex.[98] The same study transfected HEK cells with wild-type *SAMD9* and the different variants of *SAMD9*. Their results displayed markedly increased growth inhibition in the gain-of-function variants compared with wild-type, a finding that supported by a separate study with seven further variants.[98,99] This restriction in cell growth could be due to abnormalities in the endosome system and impaired extracellular-signal regulated kinase and epidermal growth factor receptor recycling.[98]

Patients from one cohort who survived the first 3 months of life all showed signs of a postzygotic loss-of-heterozygosity event, such as monosomy, deletions of 7q, or secondary somatic LOF mutations in hematopoietic cell lines, all of which have been associated with increased survival by rescuing the blood phenotype.[99] In this study, four patients possessed somatic nonsense or frameshift LOF mutations; these variants were then transfected into HEK cells along with the primary gain-of-function variants. This resulted in an increase in proliferation, indicating that the gain-of-function phenotype can be "rescued."[99] However, although monosomy or 7q deletion can lead to increased survival, it has also been shown that patients can develop myelodysplastic syndrome, a cancer that can be lethal.[98,99]

Polymerase Epsilon-1 (*POLE1*). *POLE1* encodes the essential Pol ε, the major leading-strand DNA polymerase involved in DNA replication that also possesses exonuclease ability for genetic proofreading. Somatic and germline mutations in *POLE1* have been associated with colon and endometrial cancer, but biallelic LOF mutations can also cause an IMAGe-like syndrome.[101] One study that performed whole-genome sequencing of 48 individuals with microcephalic primordial dwarfism, a set of extreme growth disorders, identified heterozygous LOF *POLE1* mutations in three patients.[101] The cohort was increased to 15 patients by identifying previously published IMAGe patients who were mutation-negative for *CDKN1C*. Of the cohort, 12 patients presented with adrenal insufficiency with variable salt wasting, and all males had genitourinary abnormalities. Interestingly, all patients possessed the same intronic variant (c.1686+32C>G) as part of a common haplotype, in combination with different LOF mutations in *trans* (11 different mutations in the 15-patient cohort).

Experiments in patient-derived fibroblasts demonstrated that the intronic variant alters splicing, and part of intron 15 is retained. This inclusion of an extra 47 bp causes a frameshift that results in an early stop codon (p.Asn563Valfs*16). This mutation, along with a LOF mutation on the other allele, significantly reduces the protein levels of POLE1 in patient fibroblasts, leading to delayed S-phase progression and, consequently, restricted cell growth.[101]

A single homozygous intronic variant (c.4444+3A>G) in *POLE1* has been associated with immunodeficiency, lymphopenia, and short stature.[102,103] Immunodeficiency was also identified in seven of the 15 patients from the discussed study, and therefore the spectrum of biallelic *POLE* mutations is greater than that of IMAGe syndrome caused by *CDKN1C* mutations.[101] A further study investigated the effect of a knock-in mutation in mice to selectively inactivate the proofreading exonuclease activity of the enzyme while preserving its normal polymerase activity.[104] This study demonstrated that the

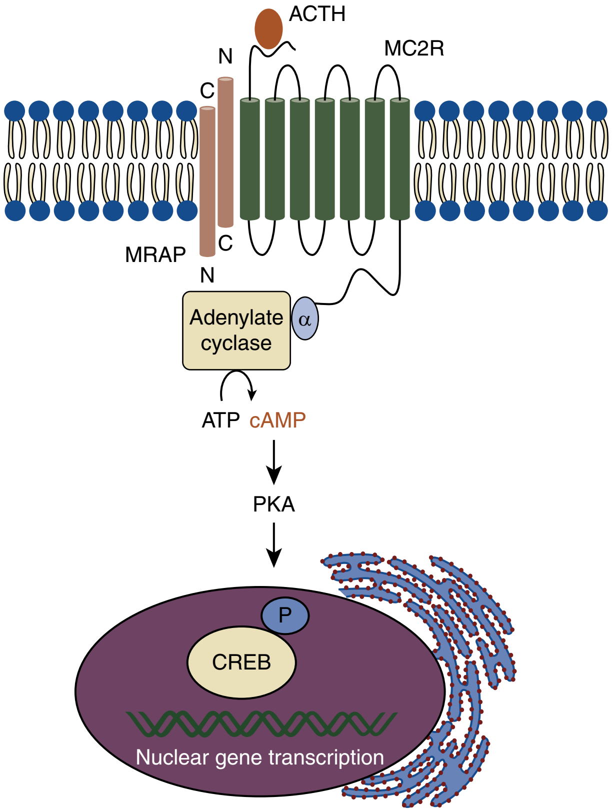

Figure 86.3 **Adrenocorticotropic hormone (ACTH) signaling in adrenocortical cells.** Ligand binding results in generation of increased levels of cAMP, which activates protein kinase A (PKA) and subsequently phosphorylates cAMP response element binding protein (CREB). CREB is directly involved in the transcriptional regulation of steroidogenic enzymes.

impaired enzyme resulted in a strong mutator phenotype with a high incidence of neoplasms.

KEY POINTS

- Familial glucocorticoid deficiency (FGD) is characterized by the lack of response to adrenocorticotropic hormone (ACTH) and results in glucocorticoid deficiency but unaffected plasma renin and aldosterone levels.
- Mutations in *MC2R* and *MRAP* cause FGD through the disruption of ACTH signaling and consequential inactivation of the steroidogenic cascade.
- *NNT* and *TXNRD2* mutations cause FGD through uncontrolled oxidative stress in the cells of the zona fasciculata, which disrupt steroidogenesis.

Familial Glucocorticoid Deficiency-Like (FGD-Like)

FGD, a hereditary unresponsiveness to ACTH, is characterized by glucocorticoid deficiency in a patient who retains normal plasma renin and aldosterone levels. It can be caused by several genes, and disease phenotypes are therefore often variable.

Melanocortin Type 2 Receptor (*MC2R*). *MC2R* encodes a G protein–coupled receptor that belongs to the melanocortin receptor family. Binding of its ligand ACTH triggers the activation of adenylate cyclase, which increases intracellular cAMP, subsequently activating PKA and the glucocorticoid steroidogenic cascade (Fig. 86.3). Mutations in *MC2R* account for the largest number of FGD cases, and the majority are nonconservative missense mutations that culminate in a failure to traffic the receptor to the cell surface, resulting in 20% to 100% reduced membrane expression in an *in vitro* study.[105,106] *MC2R* mutations were first associated with FGD via a candidate gene sequencing approach of a family with the condition in 1993.[107] More than 50 have now been described, and, interestingly, regional variants exist in *MC2R*; for example, p.S74I is the most common in the United Kingdom, while c.560delT is a recurrent mutation in Turkey.[108] Mutations in *MC2R* therefore inhibit the initiation of steroidogenesis and disrupt the negative feedback loop, resulting in high ACTH plasma levels. It is important to note that, while *MC2R* mutations most typically cause FGD, in severe LOF cases due to homozygous frameshift mutations, minor disturbances to the renin–angiotensin–aldosterone axis have been documented, therefore resulting in a form of PAI with transient mineralocorticoid deficiency.[109,110]

Patients with *MC2R* mutations typically present with symptoms of glucocorticoid deficiency, including jaundice, hypoglycemia, failure to thrive, sepsis, and hyperpigmentation.[111] Hyperpigmentation of the skin is due to supraphysiologic levels of ACTH causing overactivation of melanocortin 1 receptor (MC1R), culminating in the production of excess melanin. The age of onset is highly variable (range 0–16 years; median 2 years), with some patients presenting in later childhood with mild disease.[106] Patients present with a mean height standard deviation score of +1.76 ± 1.52,[106] believed to be due to increased ACTH-level activation of melanocortin receptors expressed in bone and cartilaginous growth plates.[112] This is supported by evidence from adrenalectomized mice showing that the melanocortin system plays a role in linear growth.[112] Interestingly, however, *Mc2r* knockout mice do not exhibit any significant difference in body length compared with wild-type mice.[113] Clinical observations indicate that the advanced growth rate in humans can be normalized with glucocorticoid replacement therapy.[114,115]

Mc2r Accessory Protein (*MRAP*). *MRAP* encodes a single transmembrane protein that acts as an essential cofactor in the trafficking of MC2R from the endoplasmic reticulum to the cell membrane to enable its functional expression.[116] It exists as a homodimer with a unique antiparallel dual topology conformation essential for its function.[117,118] Mutations in *MRAP* therefore prevent trafficking of MC2R to the plasma membrane and consequently inhibit the initiation of steroidogenesis through ACTH signaling. Mutations in the gene were first associated with FGD following linkage studies and homozygosity mapping using single nucleotide polymorphism array genotyping of a consanguineous family.[116] Unlike the majority of *MC2R* mutations, which are missense and may result in some residual function, *MRAP* mutations are typically splice-site or nonsense mutations.[106] These are predicted to result in a truncated protein that lacks the highly conserved transmembrane domain. This therefore inhibits its function of trafficking MC2R from the endoplasmic reticulum and results in degradation of the receptor.[105,116,119]

Patients with *MRAP* mutations present with the same symptoms as those with *MC2R* mutations. However, due to a complete breakdown of ACTH signaling, the disease can often present with earlier onset. One study showed that the median age of onset for *MRAP*-induced FGD was 0.08 years (compared with 2 years for *MC2R* mutations), and the range was significantly reduced, at 0 to 1.6 years.[106] Considering the earlier onset and consequential earlier glucocorticoid replacement in these patients, the taller stature seen in *MC2R* patients is largely absent in the *MRAP* patient cohort.[120] There are, however, exceptions to the rule, and sequencing of two affected families revealed homozygous missense mutations c.175T>G (pY59D) and c.76T>C (p.V26A), both of which presented with a later onset and subtler phenotype.[121] Beyond the trafficking of MC2R, MRAP has been shown to interact

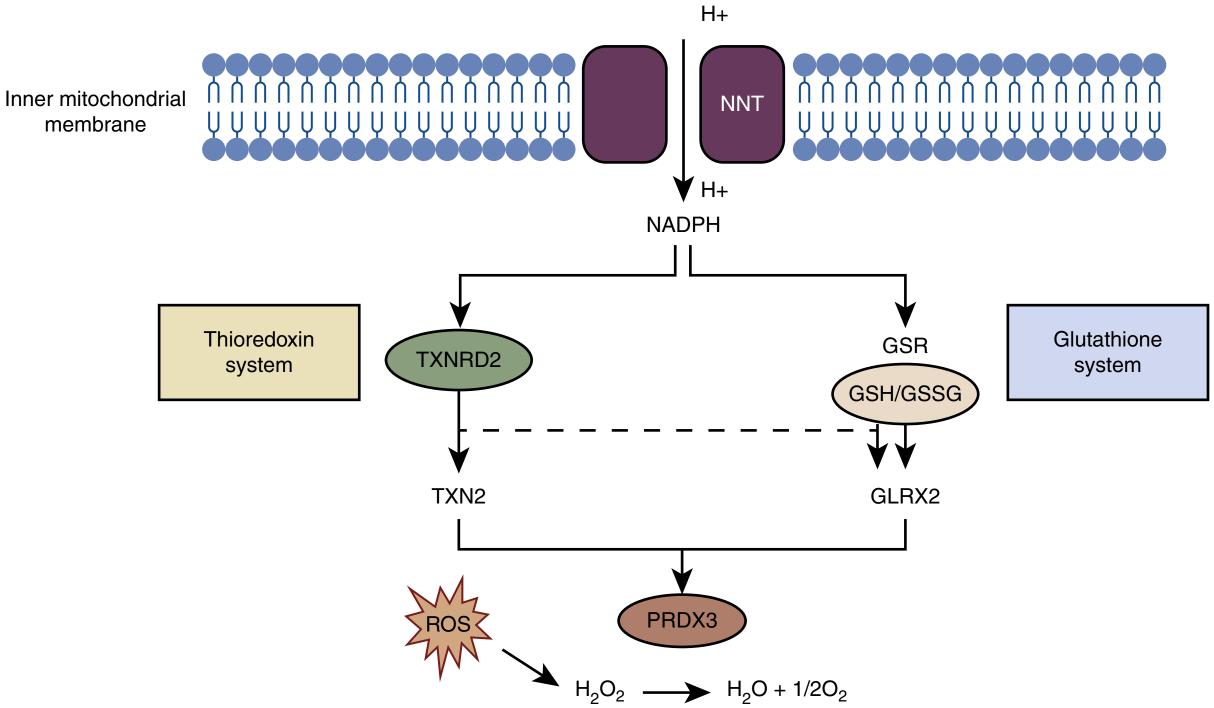

Figure 86.4 **The thioredoxin and glutathione redox homeostatic pathways.** NADPH is the electron donor that drives the thioredoxin and glutathione pathways, with NNT being the primary regenerator of NADPH levels. TXNRD2 reduces both TXN2 and GLRX2 (glutathione reductase and GSH play a further role in reduction of GLRX2), which subsequently reduces PRDX3. PRDX3, a highly conserved thioredoxin-dependent peroxide reductase, protects the cellular environment from oxidative stress due to its antioxidant properties.

with each of the melanocortin receptors, and it is postulated that its facilitation of MC4R expression could account for the obesity observed in one patient.[122,123] This remains speculative, however, and a study comparing the phenotypic differences between *MC2R* and *MRAP* patients concluded that there was no evidence that MRAP deficiency impacted any other physiological function beyond that seen with a defective MC2R.[106]

A recent study showed that *Mrap*$^{-/-}$ mice have almost complete penetrance of neonatal lethality (322 out of 325 mice) due to incomplete lung development, although this phenotype was rescuable by administration of corticosterone to pregnant dams. Mice that survived weaning showed the characteristic symptoms of MRAP deficiency: isolated glucocorticoid deficiency with normal mineralocorticoid function. Analysis of adrenal histology of knockout mice showed altered zonation, a thicker capsule, and lower mRNA expression of steroidogenic genes.[124]

Nicotinamide Nucleotide Transhydrogenase (*NNT*). NNT is the major enzymatic source of NADPH in the mitochondria, contributing 45% of the total supply.[125] Existing as a dimer, it is expressed ubiquitously throughout the body, where it spans the IMM orchestrating H^+ movement and supplying NADPH for the detoxification of reactive oxygen species (ROS) through the glutathione and thioredoxin pathways (Fig. 86.4). This role in redox homeostasis and removal of ROS contributes to limiting oxidative stress.

NNT was initially linked to PAI through single nucleotide polymorphism genotyping of consanguineous families with cases of isolated glucocorticoid deficiency, followed by targeted exome sequencing that identified many causal variants in the gene in different families.[126] This study documented 15 mutations in different kindreds that presented with a classical FGD phenotype, indistinguishable from mutations in *MC2R* and *MRAP*, with patients presenting with hypocortisolemia and elevated ACTH with normal renin and aldosterone levels. Furthermore, this study demonstrated that *NNT* mutations cause adrenal dysfunction in humans, primarily affecting cells of the zona fasciculata responsible for cortisol production, and when NNT expression was stably knocked down in adrenocortical carcinoma cells *in vitro*, increased mitochondrial ROS generation with lowered reduced glutathione to oxidized glutathione was observed.[126]

A second study reported that FGD patients with *NNT* mutations present at a median age of 12 months, with a range of 3 days to 39 months, and 53% display hyperpigmentation.[127] In a cohort of 23 patients, four presented with coexisting mineralocorticoid deficiency and showed evidence of hyponatremia, hyperkalemia, and Addisonian crises.

Further studies have added comorbidities to the classical FGD symptoms, with a cardiac phenotype being linked to *NNT* mutations. Heterozygous LOF *NNT* mutation patients have been linked to left ventricular noncompaction,[128] while a homozygous mutation (p.R379*) identified in a single patient resulted in features of glucocorticoid insufficiency with superimposed progressive left ventricular hypertrophy.[129] Furthermore, testicular adrenal rest tumors have also been documented with *NNT* mutations, similar to CAH patients.[129,130] These extra comorbidities make early screening in affected families essential.

The mouse strain C57BL/6J carries an intrinsic inactivating mutation in *Nnt* that results in an untranslated protein. Analysis of the adrenal glands of 3-month-old mice of this strain shows slightly disorganized zona fasciculata with higher levels of apoptosis than the C57BL/6N strain without this mutation.[126] A further study reported reduced steroidogenic capacity (50% reduction in corticosterone levels, perhaps due to reduction in *Cyp11a1/Cyp11b1* expression) of the adrenals due to the inability of other antioxidant enzymes to compensate for the loss of NNT, leading to oxidative stress.[131] Interestingly, C57BL/6J mice do not exhibit a cardiac phenotype, despite lacking NNT.[132]

Thioredoxin Reductase 2 (*TXNRD2*). TXNRD2 is a dimeric NADPH-dependent flavin adenine dinucleotide-containing enzyme that reduces thioredoxin 2 and other substrates.[133] It achieves this by utilizing electrons supplied by NNT (Fig. 86.4). The role of this protein, along with the glutathione system, is to eliminate ROS, which are generated in high quantities by the steroidogenic pathway and impede adrenocortical cellular function. The final step of cortisol production, performed by CYP11B1, accounts for approximately 40% of total electron flow from NADPH to ROS during steroidogenesis.[134] This may explain the susceptibility of the zona fasciculata to oxidative stress and why *NNT* and *TXNRD2* patients develop primarily glucocorticoid deficiency.

Knockdown of *TXNRD2* in adrenocortical carcinoma cells results in an increase in mitochondrial ROS levels, as it is unable to keep PRDX3 in its reduced form. This is only partially compensated for by the glutathione system.[135] Mutations in *TXNRD2* therefore can lead to oxidative stress-induced damage to mitochondria and inhibit steroidogenesis.

Thus far only one mutation of *TXNRD2* has been linked to PAI, a stop-gain mutation (p.Y447X) discovered in a Kashmiri kindred with seven affected individuals.[135] These patients presented with a wide spectrum of disease with later onset in a number of family members. All clinically affected family members demonstrated a poor cortisol response to ACTH with normal mineralocorticoid levels, and only one patient presented with a comorbidity (cardiac failure).

Txnrd2$^{-/-}$ mice exhibit embryonic lethality due to severe growth restriction, cardiac anomalies, and hematopoietic dysregulation; however, no adrenal phenotype was noted.[136] Electron microscopy of neonatal hearts showed severe swelling and destruction of mitochondrial cristae in cardiomyocytes, highlighting the damage that can be caused to mitochondria by loss of Txnrd2. This is supported by a further study that showed mitochondria isolated from *Txnrd2* knockout cardiomyocytes were unable to utilize oxygen efficiently, and consequently generated high levels of ROS.[137] Interestingly, two separate heterozygous mutations (p.G375R and p.A59T) have been identified in individuals with dilated cardiomyopathy, supporting a link between *TXNRD2* and heart failure in humans.[138]

Aladin Wd Repeat Nucleoporin (*AAAS*). Triple A syndrome (Allgrove syndrome) is a rare autosomal recessive disease caused by mutations in *AAAS*, characterized by alacrima, achalasia, and adrenal failure. It is associated with a range of progressive motor, sensory, and autonomic neurological defects.[139,140] *AAAS* encodes the nuclear pore complex protein alacrima-achalasia-adrenal insufficiency neurological disorder (ALADIN), which is expressed ubiquitously with predominance in the adrenal and central nervous system and was discovered to cause triple A syndrome in 2001.[140,141] The clinical phenotype and age of onset of the disease are highly variable, even with members of the same family, with associated features including pupil and cranial nerve abnormalities, optic atrophy, and hypoglycemic seizures.[142]

Knockdown of *AAAS* in adrenocortical carcinoma cells results in increased susceptibility to oxidative stress, along with alteration of redox homeostasis leading to apoptosis.[143,144] Furthermore, loss of AAAS has been shown to cause reduced expression of key steroidogenic enzymes STAR, mitochondrial cytochrome P450 11B1, steroid 17-alpha-hydroxylase/17,20 lyase, and steroid 21-hydroxylase, which results in a significant reduction in cortisol production in human cell lines.[143,144] Improvements in both cell viability and cortisol production were demonstrated by treatment with N-acetylcysteine, which replenishes stores of reduced glutathione and acts as a direct scavenger of free radicals.[143] This highlights the importance of the glutathione antioxidant pathway and promotes N-acetylcysteine as a possible therapeutic adjunct for triple A syndrome. Interestingly, while *Aaas* knockout mice show female infertility, they fail to develop a phenotype similar to human triple A syndrome.[145]

Mini-Chromosome Maintenance Complex Component 4 (*MCM4*). MCM4 is a protein essential for the initiation of eukaryotic genome replication. It possesses intrinsic DNA helicase activity and forms part of a hexameric complex with other MCMs. PAI appears at a higher prevalence in the Irish Traveller community, a genetically isolated population with higher levels of consanguinity than in the wider population (1 in 2506 compared with 1 in 201,898).[146] Homozygosity mapping of a cohort of Irish Travellers who were *MC2R*-, *MRAP*-, and *STAR*-mutation negative highlighted a single variant in *MCM4* (c.71-1insG) that is predicted to produce a truncated protein (p.Pro24Argfs*4).[147] This variant is unique to the Irish Traveller community and is associated with adrenal failure, growth retardation, and natural killer cell deficiency (also known as immunodeficiency 54).[147,148]

MCM4 patients present with a milder adrenal phenotype than other FGD syndromes, with onset of hypocortisolemia in childhood, sometimes following a period of normal adrenal function.[147] This is possibly explained by the presence of a shorter isoform of the protein containing all necessary functional domains and partially compensating for the loss of the full-length protein.[148] Due to its role in genome replication, *MCM4* patients suffer from chromosome fragility, increased susceptibility to viral infections, and an increased risk of developing neoplasms.[148] Mice carrying a hypomorphic allele of *Mcm4* present with capsular/subcapsular hyperplasia with nonsteroidogenic (*Cyp11b1*- and *Cyp11b2*-negative) spindle-like cells invading the cortex. This consequently reduces the number of steroidogenic cells in the zona fasciculata and is likely to reduce glucocorticoid output of the gland.[147,149]

KEY POINTS

- Primary adrenal insufficiency can also be caused by genes that do not fall into any of the above categories.
- Mechanisms include accumulation of antisteroidogenic sphingolipids (*SGPL1*), autoantibodies against steroidogenic enzymes (*AIRE*), and accumulation of toxic very long chain fatty acids (*ABCD1*, *PEX1,* and *PEX6*).

Other Causes Of Syndromic Adrenal Insufficiency

Sphingosine-1-Phosphate Lyase 1 (*SGPL1*). SGPL1 performs the final degradative step in sphingolipid metabolism. A 5’-phosphate-dependent aldehyde-lyase, it is localized to the endoplasmic reticulum, where it cleaves sphingosine 1-phosphate (S1P) and degrades it to phosphoethanolamine and hexadecanal. Loss of the enzyme can result in an accumulation of sphingolipids and proapoptotic ceramides, a feature of sphingolipidoses (Gaucher disease and Niemann–Pick disease). Conversely, in healthy conditions, its degradation of S1P makes it the major modulator of S1P signaling, which has been linked to pathways involved in angiogenesis, immune cell trafficking, stem cell differentiation, and programmed cell death.[150]

Sphingolipid intermediates including ceramide, sphingosine, and S1P are known modulators of the steroidogenic pathway.[151] In *SGPL1* patient-derived fibroblasts, elevated levels of sphingosine and ceramides result in a reduced level of cortisol production.[152] Sphingosine achieves this by acting as an endogenous antagonist of SF1, maintaining it in an inactive conformation.[153] Conversely, S1P increases cortisol secretion through promoting the expression of multiple genes involved in steroidogenesis, such as *CYP17A1* and *STAR*.[151,154] Mass spectroscopic analysis of sphingolipid intermediates in the plasma of an *SGPL1* patient and heterozygous parents revealed elevated levels of ceramide and sphingosine, and to a lesser extent S1P.[155] A further study observed a similar increase in ceramide, compared with S1P, in conditioned media from patient fibroblasts.[156] This accumulation of antisteroidogenic intermediates could explain the reduced cortisol expression seen in *SGPL1* patients.

Patients with *SGPL1* mutations are very rare, with most cases being lethal *in utero*. Those who do survive, present in infancy with multiple comorbidities, often including isolated glucocorticoid deficiency, (although mineralocorticoid deficiency has also been reported), and steroid-resistant nephrotic syndrome.[155,156] Other comorbidities include primary hypothyroidism, ichthyosis, neurodevelopmental delay, primary gonadal failure, lymphopenia, dyslipidemia, and axonal degeneration.[155-157] Cytosolic accumulations of sphingolipid intermediates, along with mitochondrial dysfunction, could be the underlying pathology behind these manifestations.[152,155]

Sgpl1$^{-/-}$ mice are born at normal Mendelian ratios, but most die within the first 2 weeks of life.[155] In mice that survive weaning, cortical zonation is compromised, with less definition between the zona glomerulosa and zona fasciculata, and with cells of the zona fasciculata appearing smaller, with fewer lipid droplets. The adrenals of the knockout mice showed lower expression of *Cyp11a1*, which supported the disruption of steroidogenesis that was observed.[155]

Autoimmune Regulator (*AIRE*). AIRE is a nuclear protein that regulates self-tolerance of T-cells, with highest expression in the thymus, and is also expressed to a lesser extent in peripheral lymphoid tissues.[158,159] Mutations in the gene cause autoimmune-poly-endocrinopathy-candidiasis–ectodermal-dystrophy syndrome (APECED) (also known as autoimmune polyendocrine syndrome), a rare monogenic autosomal recessive disease that is most common in Finnish and Iranian Jewish populations.[160] The classic criteria for diagnosis of APECED are the presence of any two of the following: chronic mucocutaneous candidiasis, chronic hypoparathyroidism, or PAI. However, the latest criteria are based on genetic and immunological features of the syndrome.[160] Dysfunctional AIRE results in the production of autoantibodies against self-antigens, including mitochondrial cholesterol side-chain cleavage enzyme, steroid 17-alpha-hydroxylase/17,20 lyase, and steroid 21-hydroxylase inhibiting steroidogenesis in the adrenals and gonads.[161] Further studies have found that almost all patients possess antibodies to interferons and interleukins, which lead to a severe autoimmune disease affecting multiple endocrine organs and other tissues.[162,163]

Initially identified in 1997 to cause APECED, to date, approximately 115 mutations have been found to affect *AIRE,* with most of these variants being either nonsense or frameshift mutations resulting in a truncated protein, or a single amino acid missense variant.[160,164,165] Due to the nature of autoimmune disease, AIRE deficiency presents with many different manifestations in a highly patient-variable manner, making the disease unpredictable. These manifestations can include mucocutaneous candidiasis, chronic hypoparathyroidism, and PAI, as well as ectodermal dystrophy, hypogonadism, vitiligo, alopecia, malabsorption, and cataracts. The most common causes of death from APECED include hypocalcemia and adrenal crisis, oral and esophageal squamous cell carcinoma, and acute hepatitis.[166] *Aire*$^{-/-}$ mice develop normally in terms of weight, size, and maturation but present with autoimmune features such as exaggerated immune response, multiorgan lymphocytic infiltration, circulating autoantibodies, and infertility, as well as undetectable adrenal glands in some mice.[167]

ATP Binding Cassette Subfamily D Member 1 (*ABCD1*). *ABCD1*, located on chromosome Xq28, encodes a protein that transports very long chain fatty acids (VLCFAs) into the peroxisome, a small membrane-enclosed organelle that contains enzyme pathways for lipid metabolism and detoxification processes.[168] Mutations in *ABCD1,* commonly missense, nonsense, or splicing-defect, result in failure to traffic VLCFAs into the peroxisome and their subsequent accumulation in plasma and tissues. VLCFAs are toxic to adrenocortical cells and also alter the structure of the cell membrane, suppressing the availability of MC2R and consequently inhibiting steroidogenesis.[169,170] Furthermore, VLCFAs are also toxic to myelin-producing oligodendrocytes, where they cause a disturbance in calcium homeostasis and mitochondrial dysfunction.[171] This toxicity caused by VLCFAs through ABCD1 dysfunction results in the genetic metabolic disorder adrenoleukodystrophy (ALD).[172]

ALD is an X-linked inheritance peroxisomal disease with two main phenotypes: cerebral demyelinating form and adrenomyeloneuropathy (AMN).[173] Sufferers of the cerebral demyelinating form of the disease appear asymptomatic at birth but start to present with cognitive dysfunction, through declining school performance and behavioral problems, between 4 and 8 years of age. The disease then progresses rapidly, with central demyelination resulting in seizures, dementia, cortical blindness, coma, and death, most frequently within 2 years of presentation and before the age of puberty.[174] The other form of the disease, AMN, presents in men in their 20s or above and is characterized by slow progressive mixed motor and sensory peripheral neuropathy, with 10% of cases developing cerebral demyelination.[175] Although all 46, XY patients with ALD are eventually affected by AMN, the age of onset and rate of progression are highly variable.[173] Virtually all 46, XY patients will develop adrenocortical insufficiency, with approximately 80% doing so before adulthood.[176]

Although ALD is deemed an X-linked disease, adrenal insufficiency can be present in 46, XX heterozygous carriers of *ABCD1* mutations.[177] In these carriers, 63% have myelopathy, whereas 57% have peripheral neuropathy, and this increases to 80% for patients over the age of 60 years.[178] This could be due to X-inactivation of the nonmutant allele, but this explanation remains contested and is not supported by this particular study.[178] One study found that *Abcd1*$^{-/-}$ mice appear normal for the first 12 months of life and show an increase in VLCFA but no demyelination in the brain, spinal cord, or peripheral nerves, indicating that VLCFAs alone may not be sufficient to demyelinate the nervous system.[179] A further study showed no statistical difference between wildtype and *Abcd1*$^{-/-}$ mice in corticosterone production or oxidative stress, while knockout of *Abcd2* resulted in the acceleration of ceroid production (lipogenic pigmentation) in the adrenal gland, the end product of oxidative damage.[180]

Peroxisomal Biogenesis Factors (*PEX* Genes). Peroxisomal diseases are divided into two main groups: disorders with a deficient enzyme or transporter (ALD), and peroxisome biogenesis disorders with multiple metabolic abnormalities, such as Zellweger spectrum disorders (ZSDs). ZSDs are autosomal recessive diseases with a range of severity due to mutations in *PEX* genes resulting in the reduction or absence of functional peroxisomes.[181] The phenotype of ZSDs is variable, depending on the *PEX* gene mutated, but the most common features are liver dysfunction, developmental delay, adrenal insufficiency, and hearing/vision impairment.[182] Adrenal insufficiency is caused by mutations in *PEX1* and *PEX6* and could be due to accumulation of VLCFAs; these are toxic to adrenocortical cells and suppress steroidogenesis, causing adrenal insufficiency in approximately 30% of patients.[169,170,183,184] Furthermore, VLCFAs are also toxic to myelin-producing oligodendrocytes, resulting in hypomyelination and neurological defects.[171]

Of the 15 *PEX* genes, mutations in *PEX1* are the most common cause of Zellweger syndrome, the most severe form of ZSDs.[185] Variants within the gene can dictate the severity of the disease. p.G843D leads to a less severe form with long survival, whereas p.Pro970* results in a nonfunctional protein, a more severe form of the disease, and shorter survival.[186-188] Indeed, nonsense mutations have been shown to result in more severe cases than missense variants.[189]

Further symptoms can include epileptic seizures, craniofacial dysmorphism, leukodystrophy, and cerebellar ataxia.[190] Zellweger disease, the most severe form, can itself be divided into three categories—neonatal-infantile, childhood, and adolescent-adult—with severity of disease decreasing as age of presentation increases. There is no curative therapy for patients, and therefore treatment is supportive and symptomatic. Hypomorphic *Pex1*-G843D mice recapitulate many of the human traits, such as adrenal insufficiency, growth retardation, and fatty liver with cholestasis.[186]

Lysosomal Acid Lipase (*LIPA*). *LIPA* encodes an enzyme that hydrolyses cholesteryl esters (CE) and triglycerides (TG) in lysosomes, producing free cholesterol and free fatty acids (FFA).[191] Free cholesterol and FFAs function as key structural components of cell membranes, energy sources, and signaling molecules. Mutations in *LIPA* result in accumulation of CE and TG all over the body, particularly the liver, spleen, lymph nodes, bone marrow, and macrophages.[191] This manifests as an autosomal recessive lysosomal storage disease with two phenotypes, presentation of which is dependent on the quantity of functional enzyme the patient possesses. Wolman disease is the early-onset form of LIPA deficiency; it presents in newborns who have no or almost no enzyme activity.[192] Sufferers of this disease rarely survive beyond infancy and present with hepatomegaly, calcification of the adrenal glands, malabsorption, and hepatic failure.[191,192] Patients who retain partial LIPA function (up to 12%) are diagnosed with CE storage disease (CESD), present later in life, if at all, and have variable clinical phenotypes.[193] Patients can present with hepatomegaly, abdominal distension, and dyslipidemia, as well as, in severe cases, multiorgan failure and death .[191] Interestingly, however, large adrenal calcium deposits are rare, although fine punctate calcifications are often detected. CESD is rare and is often misdiagnosed as nonalcoholic fatty liver disease or other forms of hypercholesterolemia.[194]

Mutations in *LIPA* have also been linked to coronary heart disease through genome-wide association studies.[195,196] This could be due to accumulation of TG and CE leading to foam cell formation and consequently atherosclerosis.[197] High levels of oxidised LDL, a result of LIPA deficiency, have been shown to result in increased levels of intracellular calcium in cultured adrenal cells, which could explain the adrenal calcification observed in Wolman disease.[198] This calcification, combined with the reduced abundance of free cholesterol, could inhibit steroidogenesis and result in a form of adrenal insufficiency in these patients.[193] LIPA deficiency can be treated by bone marrow transplant, to normalize cholesterol levels, and enzyme replacement therapy.[199,200]

Lipa$^{-/-}$ mice are born at Mendelian ratios and appear normal at birth. However, within 21 days, TG and CE accumulations appear in several organs at levels up to 30-fold higher than those found in normal mice, and the liver appears one and a half to two times larger. Adrenal glands present with an expanded adrenal cortex due to lipid accumulations. Heterozygotes have approximately 50% enzyme functionality and do not show lipid accumulation.[201]

CONCLUSION

The number of genes identified to cause PAI continues to increase, both those involved in isolated glucocorticoid deficiency and those involved in syndromic forms. With many dysfunctional genes causing similar and overlapping phenotypes, it is of vital importance to attain a genetic diagnosis for patient treatment. This process has been eased significantly with the dawn of next-generation sequencing, which allows sequencing of all genes concomitantly rather than taking a candidate gene approach. Many PAI patients remain without a genetic diagnosis, and researchers are working to identify these causative genes.

OVERVIEW OF THE HUMAN STEROIDOGENIC ENZYMES AND STEROIDOGENESIS

All steroid hormones derive from cholesterol in a process that can be conceptualized as having six distinct components:

1. *The conversion of cholesterol to pregnenolone.* Although viewed superficially as a single chemical transformation, the mobilization of cholesterol into the steroidogenic pathways is a complex event that serves as a key locus of regulation and also conventionally defines a tissue as "steroidogenic." In humans, only the cells of the adrenal cortex, testicular Leydig cells, ovarian granulosa cells, and trophoblast cells of the placenta possess high capacity to cleave cholesterol into pregnenolone (the C21 precursor of all active steroid hormones) and isocaproaldehyde, while skin and specific glial and neuronal cells of the brain have lower capacity for local synthesis. The differences in how this process is regulated and in how pregnenolone is subsequently metabolized define the roles of the various steroidogenic cells and tissues in human physiology. Unlike peptide-secreting glands, steroidogenic cells do not store steroid hormones and intermediates; it is the activation of this first step that enables the rapid synthesis and release of steroids in response to hormonal and environmental stimuli.
2. *The transformation of pregnenolone to active hormones, intermediates, and secreted steroid derivatives.* The repertoire of enzymes and cofactor proteins present in a given steroidogenic cell is responsible for the characteristic steroid profile of that cell type, and the coordinate regulation of their expression promotes the completion of all steps of a given pathway. Thus, these enzymes determine qualitatively what steroids are made, but since these steps are not kinetically limiting, it is step 1 that quantitatively regulates how much steroid is made at a given moment.
3. *Peripheral metabolism of hormones and precursors.* Although not "steroidogenic" as defined by being able to convert cholesterol to pregnenolone, some organs, such as the liver, possess tremendous capacity to transform various steroids. For example, 70% to 80% of circulating testosterone in normally cycling women derives from the conversion of adrenal dehydroepiandrosterone (DHEA). Steroids can be activated in target tissues, such as the conversion of testosterone to dihydrotestosterone (DHT) in the prostate. In contrast, active androgens and estrogens are inactivated in the uterus and in other peripheral tissues.
4. *Multiple layers of regulation.* The regulation of steroidogenesis by tropic hormones, such as adrenocorticotropic hormone (ACTH), angiotensin II, and luteinizing hormone (LH), is well known; less well appreciated are the multiple levels at which such regulation may occur. These include the transcriptional regulation of the genes encoding steroidogenic enzymes and cofactors; regulation of mitochondrial protein import; transfer of electrons from nicotinamide adenine dinucleotide phosphate (NADPH); posttranslational modification and proteosomal degradation of steroidogenic enzymes; and subcellular localization and/or targeting.
5. *Catabolism and unproductive metabolism.* A panopoly of steroids can be isolated from human plasma and tissues, many of which have negligible biological activity. Most inactive by-products derive from hepatic transformations (e.g., 6β-hydroxylation and

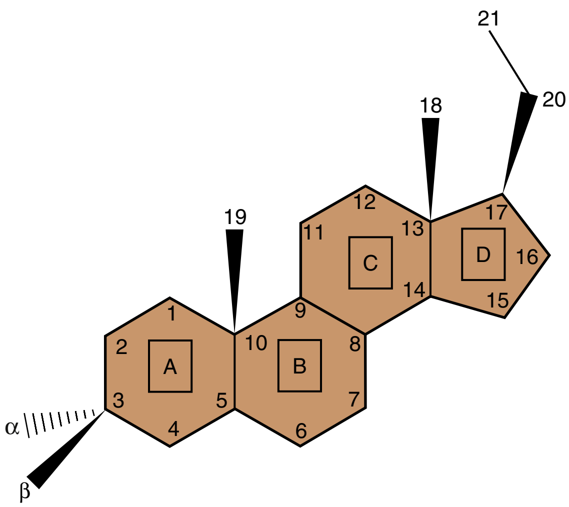

Figure 87.1 Cycloperhydropentanophenanthrene steroid nucleus. Steroid rings are identified with *boxed capital letters,* and carbon atoms are *numbered.* Substituents and hydrogens are labeled as α or β if they are positioned behind or in front of the plane of the page, respectively.

5β-reduction of C21 and C19 steroids, and 4-hydroxylation of estrogens), which promote renal excretion of these steroids.

6. *More than one pathway to specific steroids.* Particularly for the terminal steps of long pathways, such as the synthesis of DHT or estradiol, two or more routes may yield the same final product. Often the different routes utilize different enzymes, and these enzymes may be found in different tissues under different regulatory mechanisms. The relative importance of these pathways differ with age, sex, and physiologic state.

Steroids are molecules derived from the cyclopentanoperhydrophenanthrene four-ring hydrocarbon nucleus (Fig. 87.1). Most enzymes involved in steroid biosynthesis are either cytochrome P450 enzymes or hydroxysteroid dehydrogenases (Fig. 87.2).[1] All P450-mediated hydroxylations and carbon–carbon bond cleavage reactions are mechanistically and physiologically irreversible. Hydroxysteroid dehydrogenase reactions are mechanistically reversible and can run in either direction under certain conditions *in vitro*, but each hydroxysteroid dehydrogenase drives steroid flux predominantly in either the oxidative or reductive mode *in vivo*.[2] However, two or more hydroxysteroid dehydrogenases drive the flux of a steroid pair in opposite directions, some favoring ketosteroid reduction and others favoring hydroxysteroid oxidation.

KEY POINTS

- The conversion of cholesterol to pregnenolone is the quantitative, rate-limiting step of steroidogenesis and the site of acute regulation.
- Steroidogenesis follows a specific sequence with some branch points and redundancies, and each step is either irreversible or has a strong directional preference.
- Steroid formation features multiple layers of regulation, redundancy for some pathways, and multiple activities for some key enzymes.

Cytochrome P450 Enzymes

Mammalian cytochrome P450 enzymes fall into two broad classes: type 1 and type 2.[1] Type 1 enzymes and their electron transfer proteins reside in the mitochondria (Table 87.1) of eukaryotes; almost all bacterial P450s are also type 1 enzymes. Human type 1 P450 enzymes include the cholesterol side-chain cleavage enzyme (P450scc); the two isozymes of 11-hydroxylase (P450c11β and P450c11AS); and three of the principal enzymes in vitamin D metabolism (1α-hydroxylase, 24-hydroxylase, and 25-hydroxylase). Type 1 enzymes receive electrons from the reduced form of NADPH via ferredoxin (FDX1), a small, soluble, iron-sulfur protein. FDX1 does not oxidize NADPH directly, however, but receives the two electrons from NADPH via the flavoprotein ferredoxin reductase (FDXR, Fig. 87.3). Type 2 enzymes, in contrast, receive electrons from NADPH via the flavin adenine dinucleotide (FAD)-flavin mononucleotide (FMN) two-flavin protein, P450 oxidoreductase (POR). Type 2 enzymes are exclusively located in the smooth endoplasmic reticulum and constitute 50 of the 57 human P450 enzymes.

P450 enzymes activate molecular oxygen using their heme center and electrons from NADPH. Substrate binding is required prior to heme reduction with one electron, which enables oxygen binding, the second one-electron transfer, and formation of the iron-oxygen complex, which then oxygenates the substrate. Thus, P450 reactions on steroids are limited to oxygen insertion (hydroxylation) reactions and, in a few notable cases, oxidative carbon–carbon bond cleavage reactions (Table 87.2).

Hydroxysteroid Dehydrogenases and Reductases

All hydroxysteroid dehydrogenases (HSDs) and related enzymes use nicotinamide cofactors either to reduce or to oxidize the steroid by two electrons through a hydride transfer mechanism.[1] Most examples involve the conversion of a secondary alcohol to a ketone or vice versa, and in the case of the 3β-hydroxysteroid dehydrogenase/$\Delta^5 \rightarrow \Delta^4$-isomerases, the dehydrogenation is accompanied by the isomerization of the adjacent carbon–carbon double bond from the Δ^5 (between carbons 5 and 6) to the Δ^4 positions (see Figs. 87.1 and 87.2). The human steroid 5α-reductases types 1 and 2, which are included with the HSDs for convenience, reduce olefinic carbon–carbon double bonds to the saturated state rather than acting on carbon centers bonded to oxygen.

The HSDs can be categorized according to either structural or functional classification schemes. *Structurally*, HSDs are members of either the short-chain dehydrogenase reductase (SDR) or aldo-keto reductase (AKR) families.[2] The SDR enzymes are β-α-β proteins, where up to seven parallel β-strands fan across the center of the molecule, forming the "Rossman fold" characteristic of oxidation/reduction enzymes that use nicotinamide cofactors. The AKR enzymes are soluble proteins that contain a beta-barrel or triose-phosphate isomerase (TIM-barrel) motif in which eight parallel β-strands lie in a slanted circular distribution like the staves of a barrel. In both cases, the active site contains a critical tyrosine and lysine pair of residues involved in proton transfer from or to the steroid alcohol during catalysis. *Functionally,* HSDs act either as true dehydrogenases, using NAD^+ as a cofactor to convert hydroxysteroids to ketosteroids; or as ketosteroid reductases, utilizing predominantly NADPH to reduce ketosteroids. Many HSDs catalyze either oxidation or reduction *in vitro* based on the pH and cofactor concentrations, but these enzymes, when expressed in intact mammalian cells, drive steroid flux primarily in one direction.[2] These directional preferences derive primarily from the relative abundance of the oxidized and reduced form of cofactors and the relative affinity of each enzyme for NAD(H) versus NADP(H) because cofactor concentrations exceed steroid concentrations by many orders of magnitude.[2] Consequently, the directional preference of some "reductive" enzymes can be reduced or reversed by depleting cells of NADPH or by mutations that attenuate the preferential binding of NADPH over NAD(H).[3,4]

Figure 87.2 **Major human steroidogenic pathways.** Key enzymes and cofactor proteins are shown near *arrows* indicating chemical reactions. The steroidogenic acute regulatory protein (StAR) protein *(oval)* mobilizes cholesterol from the outer mitochondrial membrane to the inner mitochondrial membrane, where P450scc cleaves cholesterol to pregnenolone, the first committed intermediate in steroid biosynthesis. The steroids in the *first column* are Δ^5-steroids, which constitute the preferred pathway to C19 steroids in humans, and the *dashed arrow* indicates poor flux from 17α-hydroxyprogesterone to androstenedione. Steroids in the *second column and farther right* are Δ^4-steroids, except the C18 estrogens (estrone and estradiol) and 5α-reduced steroids, including the potent androgen dihydrotestosterone and other androstanes *(bottom row)*. *Diagonal arrows* indicate additional pathways from 17α-hydroxyprogesterone (backdoor pathway) and androstenedione (11-oxygenated androgens) illustrated in Fig. 87.7. Not all intermediate steroids, pathways, and enzymes are shown.

KEY POINTS

- The two major classes of steroid biosynthetic enzymes are cytochrome P450 enzymes and the hydroxysteroid dehydrogenases/reductases.
- Of the steroidogenic cytochrome P450 enzymes, P450scc, P450c11β, and P450c11AS are mitochondrial and use ferredoxin/ferredoxin reductase as electron transfer proteins; P450c17, P450c21, and P450aro reside in the endoplasmic reticulum and use P450-oxidoreductase as their electron transfer protein.
- The hydroxysteroid dehydrogenases catalyze mechanistically reversible oxidation/reduction reactions using NAD[P][H] cofactors; some enzymes strongly favor hydroxysteroid oxidation, and others strongly favor ketosteroid reduction in intact cells.

Acute Regulation of Steroidogenesis

Every time a pulse of ACTH reaches the adrenal cortex, or a pulse of LH reaches the gonad, a subsequent pulse of steroid hormone production is observed within minutes. Although it has long been known that the loss of trophic hormones from the pituitary gland leads to adrenal and gonadal atrophy, the action of ACTH and LH to promote organ survival and to maintain steroidogenic capacity occurs at three distinct levels. First, as seen in long-term exposure to ACTH (e.g., in Cushing disease), ACTH promotes adrenal growth. This growth occurs primarily by ACTH stimulating the production of cyclic adenosine monophosphate (cAMP), which, in turn, promotes the synthesis of insulin-like growth factor 2 (IGF-2), basic fibroblast growth factor,

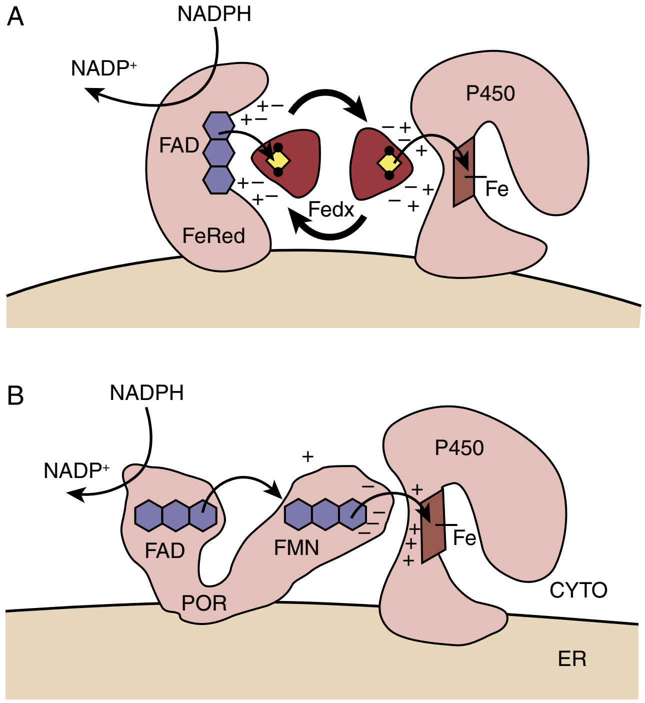

Figure 87.3 Electron transfer pathways for steroidogenic cytochrome P450 enzymes. A, In type I (mitochondrial) enzymes, the two electrons from the reduced form of nicotinamide adenine dinucleotide phosphate (NADPH) pass from the flavin (FAD) of ferredoxin reductase (FeRed) to the iron-sulfur (Fe2S2, diamond with dots) cluster of ferredoxin (Fedx) and then to the heme of the P450 *(square with Fe).* Negatively charged residues in Fedx (–) guide docking and electron transfer with positively charged residues (+) in both Fedx and the P450. **B,** In type II (microsomal) enzymes, the flavoprotein P450-oxidoreductase (POR) receives electrons from NADPH to its FAD moiety, transfers electrons to its FMN moiety, and after a conformational rearrangement, directly transfers electrons from the FMN to the P450. Negative charges on POR (–) and positive charges (+) on the P450 guide the interaction as with the type I P450; with some P450 enzymes, phosphorylation and cytochrome b5 also regulate electron transfer and catalysis. Heme of P450 is indicated by a *square* with iron atom (Fe).

and epidermal growth factor. Together, these growth factors stimulate adrenal cellular hypertrophy and hyperplasia. Second, ACTH acts long-term through cAMP, and angiotensin II acts through the calcium/calmodulin pathway to promote the transcription of genes encoding various steroidogenic enzymes and electron-donating cofactor proteins. Third, ACTH fosters the increased flow of cholesterol into the mitochondria, where it becomes substrate for the first and rate-limiting enzyme, P450scc. This acute response occurs within minutes and is inhibited by inhibitors of protein synthesis (e.g., puromycin or cycloheximide), indicating that a short-lived protein species mediates this process. Although other proteins are involved in the chronic replenishment of mitochondrial cholesterol, abundant biochemical, clinical, and genetic evidence implicates the steroidogenic acute regulatory protein (StAR) as this labile protein mediator.[5]

StAR is a 37-kD phosphoprotein that is cleaved to a 30-kD form when it enters the mitochondrion. Overexpression of mouse StAR in mouse Leydig MA-10 cells increased their basal steroidogenic rate,[5] and cotransfection of expression vectors for both StAR and the P450scc system in nonsteroidogenic COS-1 cells augmented pregnenolone synthesis above that obtained with the P450scc system alone.[6] Mutations in StAR cause congenital lipoid adrenal hyperplasia,[6,7] in which very little steroid is made; and targeted disruption of the *Star* gene in the mouse causes a similar phenotype.[8]

The mechanism of StAR's action is not completely understood. After other proteins transport cholesterol to the mitochondria, StAR acts on the outer mitochondrial membrane (OMM),[9] and its activity in promoting steroidogenesis is proportional to its residency time on the OMM.[10] When expressed in cytoplasm or added to mitochondria *in vitro*, both the 37-kD "precursor" and the 30-kD "mature form" of StAR are equally active, but StAR is inactive in the mitochondrial intramembranous space or matrix.[10] Thus, it is StAR's cellular localization, not its cleavage, that determines whether or not it is active. StAR has a sterol-binding pocket that accommodates a single molecule of cholesterol.[11] The interaction of StAR with the OMM involves conformational changes[12] that are necessary for StAR to accept and discharge cholesterol molecules. Although StAR can transfer cholesterol between synthetic membranes *in vitro*, suggesting that other protein molecules are not needed for its action, this activity can also be seen with the inactive mutant R182L, which causes lipoid congenital adrenal hyperplasia.[13] Thus StAR's action to promote steroidogenesis can be dissociated from its cholesterol-transfer activity. StAR appears to interact with a complex of OMM proteins that includes the peripheral benzodiazepine receptor (PBR, also termed the *translocator protein* [TSPO]), voltage-dependent anion channel 1 (VDAC1), the acyl-CoA-binding-domain proteins ACBD-1 and ACBD-3, and possibly others. Each molecule of StAR appears to be recycled, moving hundreds of molecules of cholesterol before the cleavage/inactivation event.[14] Although StAR is required for the acute steroidogenic response, steroidogenesis will persist in the absence of StAR at approximately 14% of the StAR-induced rate, accounting for the steroidogenic capacity of tissues that lack StAR (e.g., the placenta and the brain). TSPO ligands stimulate testosterone production in rats,[15] yet mice with targeted deletion of the *Tspo* gene in Leydig cells have normal stimulated testosterone production and are fertile.[16] These paradoxical findings suggest that more than one protein complex or cholesterol transfer mechanism can contribute to steroidogenesis in specific cells.

Chronic Maintenance of the Steroidogenic Machinery

The acute regulation of steroidogenesis is determined by access of cholesterol to the P450scc enzyme, and P450scc is the rate-limiting enzymatic step in steroidogenesis. Thus, the chronic regulation of steroidogenesis is quantitatively (how much) determined by *CYP11A1* (encoding P450scc) expression[17] and qualitatively (which steroids) determined by the expression and activities of downstream enzymes. The episodic bursts of cAMP resulting from the binding of ACTH and LH to their respective receptors are necessary but not sufficient for the continued expression of the steroidogenic enzymes and the production of steroids. Patients with inactivating mutations in the ACTH receptor (melanocortin type 2 receptor, MC2R)[18] or LH receptor[19] make negligible amounts of steroids from the affected glands. Conversely, activating mutations of the Gsα protein, which couples receptor binding to cAMP generation, and activating mutations of the LH receptor cause hypersecretion of steroids.[20] Indeed, cAMP-responsive elements have been identified in the genes for most of the human steroidogenic P450 enzymes, but this mechanism alone does not account for the diversity of steroid production observed in the various zones of the adrenal cortex, the gonads of both sexes, the placenta, and the brain.

Other transcription factors (e.g., AP-2, SP-1, SP-3, NF1C, NR4A1, NR4A2, GATA4, and GATA6) aid in defining the basal- and cAMP-stimulated transcription of each gene, which is also regulated in a tissue-specific manner by the regulatory elements unique to each gene. Among these factors, steroidogenic factor-1 (SF-1, NR5A1), an orphan nuclear receptor, coordinates the expression of steroidogenic enzymes

*Steroids in brackets are poor substrates.

in adrenal and gonadal cells.[21] By contrast, steroidogenesis in the brain and placenta[22] is independent of SF-1. Targeted disruption of SF-1 in the mouse not only disrupts steroid biosynthesis but also blocks the development of the adrenal glands, gonads, and the ventromedial hypothalamus in homozygous animals.[23] Furthermore, SF-1 does not act in isolation, but its action is modified by other transcription factors (e.g., WT-1 and DAX-1)[24] or by phosphorylation.[25] Thus, the development of steroidogenic organs is intimately related to the capacity to produce steroids, and multiple factors acting on the genes for steroidogenic enzymes yield both common features and diversity among the steroidogenic tissues.

Most steroidogenic enzymes derive from a single mRNA species. The most prominent exception to this paradigm is aromatase, whose gene has four different promoters that enable vastly different regulation of expression of the same aromatase protein in many different tissues.[26]

KEY POINTS

- The acute regulation of steroidogenesis is determined by access of cholesterol to the P450scc enzyme, and P450scc is the rate-limiting enzymatic step in steroidogenesis.
- Adrenocorticotropic hormone in the adrenal cortex, and luteinizing hormone in the gonad, stimulate this first step by the influx of cholesterol, mediated by steroidogenic acute regulatory protein.

HUMAN STEROIDOGENIC CYTOCHROME P450 ENZYMES

P450scc (Encoded by *CYP11A1*)

P450scc consumes three equivalents of NADPH and molecular oxygen during the conversion of cholesterol to pregnenolone. Although the enzyme is named for the cleavage of the cholesterol side chain, this process consists of three discrete steps: 1) the 22-hydroxylation of cholesterol; 2) the 20-hydroxylation of 22(R)-hydroxycholesterol; and 3) the oxidative scission of the C20–C22 bond of 20(R), 22(R)-dihydroxycholesterol—the side-chain cleavage event. The enzyme will utilize free hydroxysterol intermediates as substrates for the side-chain cleavage reaction, a tool that is used experimentally because the hydroxysterols are much more soluble than cholesterol and because their access to P450scc is independent of StAR.[6] *In vivo*, however, little of these free intermediates probably accumulate, because their k_{cat}/K_m ratios are much higher than for cholesterol,[27] and the high K_D for pregnenolone (approximately 3000 nM) drives product dissociation. This complex process is the rate-limiting step in steroidogenesis, with turnover numbers of only approximately 20 molecules of cholesterol per molecule P450scc per minute,[27] and all three reactions utilize the iron oxene (compound I) species without incorporation of dioxygen atoms into pregnenolone or isocaproaldehyde during the third reaction.[28] The x-ray crystal structure of the P450scc–ferredoxin complex shows that cholesterol substrate binds with the steroid nucleus angled to approximately 45 degrees with the heme ring, with the side chain extended across the heme,[29] which is consistent with the known order of reactions. P450scc will also cleave the side chain of other hydroxysterols (e.g., 7-dehydrocholesterol), and 20- and 22-hydroxylates vitamin D.

The *CYP11A1* gene (Table 87.2) encodes an mRNA of 2 kb. Following translation, a 39-amino acid mitochondrial leader peptide that targets P450scc to the mitochondria is then proteolytically removed to yield a 482-amino acid protein. Forms of P450scc engineered to lack the mitochondrial leader are inactive,[30] demonstrating that the mitochondrial environment is required for activity. Expression of P450scc is induced in the adrenal zonae fasciculata and reticularis,[31] testis, and ovary by cAMP; and in the zona glomerulosa by intracellular calcium/protein kinase C.[32] In contrast, placental P450scc expression is constitutive and is caused at least in part by the long terminal repeat-binding protein family of transcription factors.[22] Side-chain cleavage activity and pregnenolone biosynthesis have been demonstrated in the rat and human brain[33]; and abundant P450scc expression is found in the rodent brain, especially in fetal life. Deletion of the gene for P450scc has been described in rabbits and mice,[34] abrogating all steroidogenesis and thus proving that P450scc is the only enzyme that can convert cholesterol to pregnenolone. While homozygous mutations in P450scc might be expected to be embryonic lethal by eliminating placental progesterone synthesis, patients have been described having P450scc mutations that typically retain partial enzymatic activity.[35]

P450c17 (Encoded by *CYP17A1*)

P450c17 catalyzes both the 17α-hydroxylase and 17,20-lyase reactions,[36] with additional regulatory mechanisms for the 17,20-lyase reaction.

The *CYP17A1* gene (Table 87.2) encoding P450c17 is expressed in the adrenals and gonads,[37] and leads to a single 2.1-kb mRNA species yielding a 57-kD protein in these tissues; mutations in this gene produce a spectrum of deficiencies in 17-hydroxysteroids and C19 steroids.[38]

Human P450c17 17-hydroxylates both pregnenolone and progesterone with approximately equal efficiency, but all other reactions show prominent differences among substrates. The 17,20-lyase activity is approximately 50 times more efficient for the 17α-hydroxypregnenolone-to-DHEA reaction than for the 17α-hydroxyprogesterone-to-androstenedione reaction.[39] Although the rate of the lyase reaction can be increased more than 10-fold by the addition of a molar equivalent of cytochrome b5,[39] the Δ^5 preference persists, and the lyase rate never quite reaches the rate of the hydroxylase reactions. Residue N202 of P450c17 serves as a hydrogen bond donor (NH) to the 3-keto oxygen of Δ^4 steroids or acceptor (CO) for the 3-hydroxyl hydrogen of Δ^5 steroids,[40] and mutation N202S eliminates the Δ^5 preference for the 17,20-lyase reaction.[41] In addition, human P450c17 16α-hydroxylates progesterone but not pregnenolone,[39] and, in the presence of cytochrome b5, diverts approximately 10% of pregnenolone metabolism to a Δ^{16} andiene product that is also formed by this pathway in pigs and that acts as a porcine pheromone. Although experiments to study the chemistry of human P450c17 often require manipulations that could be considered nonphysiologic, the remarkable consistency for substrate preferences and kinetic constants observed for the modified, solubilized P450c17 expressed in *Escherichia coli* and native P450c17 expressed in yeast microsomes, or intact COS-1 cells, or that obtained from human tissues and cells, serve to verify these conclusions.

In addition, the 5α-reduced C21 steroids dihydroprogesterone (5α-pregnane-3,20-dione) and allopregnanolone (5α-pregnan-3α-ol-20-one) are excellent substrates for the 17α-hydroxylase activity of P450c17.[42] Furthermore, 17α-hydroxylated allopregnanolone (5α-pregnane-3α,17α-diol-20-one) is the most efficient substrate yet identified for the 17,20-lyase activity of human P450c17, and its cleavage to androsterone is minimally dependent on cytochrome b5,[42] unlike 17α-hydroxypregnenolone metabolism to DHEA.[39] The conversion of 5α-pregnane-3α,17α-diol-20-one to androsterone by the 17,20-lyase activity of P450c17, first described in the testes of tammar wallaby pouch young,[43] provides an alternative or "backdoor" pathway to DHT (discussed later), by which DHT is produced without utilizing DHEA, androstenedione, and testosterone as intermediates. Consequently, the presence of 5α-reductases in steroidogenic cells does not preclude the production of C19 steroids, but rather paradoxically enhances the production of DHT by directing flux to 5α-reduced precursors of DHT. Human enzymes catalyze all of the other reactions required to complete this alternate route to DHT,[44] and the fetal adrenal gland produces 5α-reduced androgens, at least in some pathologic states. The backdoor pathway provides a major route to DHT in pathologic states in which 17α-hydroxyprogesterone accumulates, including 21-hydroxylase deficiency and P450 oxidoreductase deficiency.[45] Androgen production by the backdoor pathway probably contributes to the severe virilization in newborn girls with 21- and 11-hydroxlase deficiencies, while those with 3β-HSD2 deficiency, whose adrenal glands cannot make 17α-hydroxyprogesterone, are minimally virilized.[46] Furthermore, 11-oxygenated pregnanes are also substrates for human P450c17, which can generate 11-oxygenated androgens.[47]

The chemistry of P450c17-mediated hydroxylations is believed to proceed via the common iron oxene species and "oxygen rebound" mechanism proposed for prototypical P450 hydroxylations.[48] The mechanism(s) of the 17,20-lyase reaction involving a carbon–carbon bond cleavage, however, is not resolved, despite considerable study. The capacity of chemically formed iron oxene,[48] but not hydrogen peroxide alone, to support catalysis suggest that the same heme-oxygen complex might participate in both hydroxylations and the 17,20-lyase reaction, but spectroscopic studies suggest the participation of a peroxy-anion intermediate.[49] The sequential reactions follow distributive rather than processive kinetics,[50] meaning that the intermediate 17-hydroxysteroids are released from the active site prior to the 17,20-lyase reaction.

One consequence of the Δ^5 preference of the human enzyme for the 17,20-lyase reaction is that most human C19- and C18-steroids derive from DHEA as an intermediate. This Δ^5 preference allows for the phenomenon of adrenarche to occur in humans, an event that only takes place in large primates.[51] However, Δ^5-lyase activity is not sufficient for adrenarche to occur, because some monkeys (e.g., rhesus macaques) produce high amounts of DHEA throughout life, but most mammals (e.g. cattle, dogs, cats) never produce much DHEA.[51] The biochemistry of P450c17, with its differential regulation of 17α-hydroxylase and 17,20-lyase activities, provides clues to the genesis of this enigmatic process of adrenarche. P450c17 is a phosphoprotein, and phosphorylation selectively enhances the 17,20-lyase activity.[52] Mitogen-associated kinase p38α (MAPK14), can phosphorylate P450c17 and confer 17,20-lyase activity to recombinant P450c17 *in vitro* and in immortalized cell systems,[52] and this kinase activity is counterbalanced by protein phosphatase 2A, which in turn is regulated by cAMP via phosphoprotein SET.[53] Cytochrome b5 also augments 17,20-lyase activity, and high expression of b5 in the zona reticularis of monkeys and humans[54] suggests that the developmentally regulated expression of cytochrome b5 might be a key event. The transcriptional regulation of cytochrome b5 in the adrenal gland is similar to that of P450c17,[55] and the mechanisms enabling zone-specific expression have not been elucidated. Finally, limiting steroid flux to the Δ^5 pathway by low 3β-HSD activity in the zona reticularis (where most DHEA derives) potentiates the effect of increased 17,20-lyase activity.[54,56]

The initial description of 17α-hydroxylase deficiency was a case in which both 17α-hydroxylase and 17,20-lyase products were absent.[57] When the gene for human P450c17 was cloned, patients with 17α-hydroxylase deficiency were found to harbor mutations in the *CYP17A1* gene, and approximately 100 mutations scattered throughout the *CYP17A1* gene have been characterized.[38] Mutations in W406R and R362C accounted for the high prevalence of 17α-hydroxylase deficiency in Brazil,[58] and triple deletion of D487, S488, F489, and Y329fs accounted for most cases of 17α-hydroxylase deficiency in China and Southeast Asia.[38]

Isolated 17,20-lyase deficiency is extremely rare, mainly caused by mutations in arginines 347 and 358.[59,60] Computer modeling studies demonstrate that R347H and R358Q neutralize positive charges in the redox-partner binding site.[59] Biochemical studies confirm that mutations R347H and R358Q impair interactions of P450c17 with its electron donor POR and with cytochrome b5.[61] Therefore, these cases of isolated 17,20-lyase deficiency are not caused by an inability of the mutant enzymes to bind the intermediate 17α-hydroxypregnenolone, but rather the uncoupling of electron transfer with catalysis.[59,61,62] In contrast, mutation E305G has been shown to cause 17,20-lyase deficiency by selectively disrupting binding of 17α-hydroxypregnenolone and DHEA synthesis despite enhanced conversion of 17α-hydroxyprogesterone to androstenedione.[63] This unusual variant of isolated 17,20-lyase deficiency provides further genetic evidence that the flux of androgens derived from conversion of 17α-hydroxyprogesterone to androstenedione in the minor Δ4 pathway is not sufficient to form normal male external genitalia. Mutation V366M is thought to selectively impair 17,20-lyase activity by interfering with substrate binding and egress.[64] One of the first patients reported to have isolated 17,20-lyase deficiency bears a homozygous mutation in P450 oxidoreductase (G539R), further emphasizing the crucial role of efficient electron transfer in the 17,20-lyase reaction.[65] Apparent isolated 17,20-lyase deficiency may also be caused by specific mutations in cytochrome b5.[66,67]

The P450c17 inhibitors ketoconazole and abiraterone are used to treat castration-resistant prostate cancer (CRPC) by suppressing testosterone production beyond limits achieved with medical or surgical castration.[68] The x-ray crystal structures of modified human P450c17 with bound abiraterone or galeterone (TOK-001) show the azole nitrogens bound to the heme iron with the α-face of the steroid facing the heme and the A-ring draped against the I-helix.[69] These structures explain the 17α-hydroxylation chemistry of P450c17 and suggest that the 17,20-lyase reaction involves oxidation from the α-face as well.

KEY POINTS

- The 17-hydroxylase and 17,20-lyase activities of P450c17 qualitatively regulate the type of steroid hormones produced in a cell.
- Cytochrome b_5 augments the 17,20-lyase activity of P450c17 10-fold by increasing the coupling of electron transfer to substrate oxidation.

P450c21 (Encoded by *CYP21A2*)

Microsomal P450c21 performs adrenal 21-hydroxylation of the Δ4 steroids 17α-hydroxyprogesterone and progesterone, an essential step in the biosynthesis of both mineralocorticoids and glucocorticoids (see Fig. 87.2). The human P450c21 protein is found only in the adrenal glands; the extra-adrenal 21-hydroxylase activity found in other organs such as the liver and the aorta is not catalyzed by P450c21 but appears to be catalyzed by CYP2C9, CYP3A4, and possibly CYP2C19 and other enzymes as well.[70]

The locus containing the *CYP21* genes is among the most complex in the human genome and explains why 21-hydroxylase deficiency (affecting approximately 1 in 14,000 live births) is one of the most common autosomal-recessive diseases. The *CYP21A2* gene and the *CYP21A1P* pseudogene lie on chromosomal locus 6p21.1 in the midst of the human leukocyte antigen (HLA) locus. Because the HLA locus is highly recombinogenic, exchange between the *CYP21A1P* and *CYP21A2* loci is common. Thus, approximately 95% of 21-hydroxylase mutations derive from gene micro- or macroconversion events where some or all of the *CYP21A1P* pseudogene replaces the corresponding area of the *CYP21A2* gene, thus reducing the expression of the encoded P450c21 protein and/or impairing its activity.[71] Most of the remaining mutations causing 21-hydroxylase deficiency are *CYP21A2* gene deletions, again caused by recombination events; only approximately 1% of *CYP21A2* mutations do not occur via recombination. In addition, at least eight additional genes lie in this locus (Fig. 87.4), including the liver-specific C4A and C4B genes and the ubiquitously expressed tenascin X or *TNXB* gene, the disruption of which is one cause of Ehlers–Danlos syndrome (EDS). Occasionally, a patient with 21-hydroxylase deficiency and EDS will have a contiguous gene syndrome with tenascin-X deficiency as well.[72] Heterozygosity for TNXB causes a mild form of EDS characterized by joint hypermobility, and up to 7% of patients with classic CAH also have this form of EDS.[73]

It is clear that genotype consistently predicts phenotype in very severe and very mild cases of 21-hydroxylase deficiency. In contrast, patients with P450c21 variants (e.g., the common P30L and V281L mutations and the less common R339H and P453S mutations), which have 5% to 20% of wild-type activity, can have various phenotypes, implying additional factors that can modify the clinical manifestations of 21-hydroxylase deficiency.[71]

Unlike P450c17, P450c21 is not very sensitive to the abundance of POR or regulated via cytochrome b5. The x-ray crystal structure of bovine P450c21 contains two molecules of bound steroid, one with the steroid nucleus perpendicular to the heme ring, so positioning the C-21 hydrogen atoms directly above the heme iron for hydroxylation.[74] The second steroid molecule lies toward the periphery of the enzyme and is unlikely to undergo hydroxylation, but it may contribute to enzyme structure or allostery. The structure of human P450c21 contains only the progesterone molecule in the active site with V359 holding the steroid in place.[75] Mutation of V359 to the smaller residues alanine and glycine increases progesterone mobility and confers 16α-hydroxylase activity to the enzyme.[76] The 21-hydroxylase reaction of human P450c21 shows large intra- and intermolecular kinetic isotope effects,[77,78] meaning that C-H bond breaking is substantially rate-limiting. Impairments of substrate binding, catalysis, heme incorporation, and thermal stability are observed for the common mutations causing varying degrees of 21-hydroxylase deficiency.[79]

KEY POINTS

- The *CYP21* gene locus lies within the is highly human leukocyte antigen complex, and recombination exchange between the *CYP21A1P* and *CYP21A2* loci is common.
- 21-hydroxylase deficiency is one of the most common autosomal recessive disorders.
- Genotype predicts phenotype in very severe and very mild cases of 21-hydroxylase deficiency.

P450c11β and P450c11AS (Encoded by *CYP11B1* and *CYP11B2* in Humans)

The classical descriptions of distinct deficiencies in 11β-hydroxylase, 18-hydroxylase (previously called corticosterone methyl oxidase I or CMOI), and 18-oxidase (CMOII) suggested that three enzymes executed these three respective transformations. Analogous to the scenario for P450c17, a single enzyme[80] and corresponding gene were found in bovine adrenal glands that possessed all three activities. In contrast, humans have two genes named *CYP11B1* and *CYP11B2*[81] that encode the mitochondrial enzymes 11β-hydroxylase (P450c11β) and aldosterone synthase (P450c11AS), respectively, and rats, but not mice, have three functional *Cyp11b* genes. Although P450c11β and P450c11AS both possess 11β-hydroxylase activities, P450c11AS also performs the two oxygenations at C18 required for aldosterone biosynthesis.[82] P450c11β catalyzes a small amount of 18-hydroxylase but no 18-oxidase activity.[83] Mutations in *CYP11B1* cause 11β-hydroxylase deficiency,[84] whereas defects in *CYP11B2* cause variable aldosterone synthase deficiency, with salt wasting, failure to thrive, and hypotension.[85] Severe defects can impair all P450c11AS activities, leading to the clinical phenotype of CMOI deficiency,[82] while P450c11β provides 11β-hydroxylase activity in the zona fasciculata. Fortuitously, mutations R181W plus V386A, which mainly impair 18-oxidase activity, are found in patients and cause CMOII deficiency.[86]

Unlike the multistep distributive kinetics of P450scc and P450c17, P450c11AS uses a highly processive mechanism to synthesize aldosterone from deoxycorticosterone (DOC) without release of the intermediates.[87] Consequently, more aldosterone is formed and at a faster rate using DOC as the substrate than corticosterone, even though one additional step is required. Furthermore, only a trace of aldosterone is formed from 18-hydroxycorticosterone, presumably due to formation of a cyclic acetal in solution with unfavorable geometry, which may explain why a processive mechanism from DOC is essential for efficient aldosterone synthesis.[87]

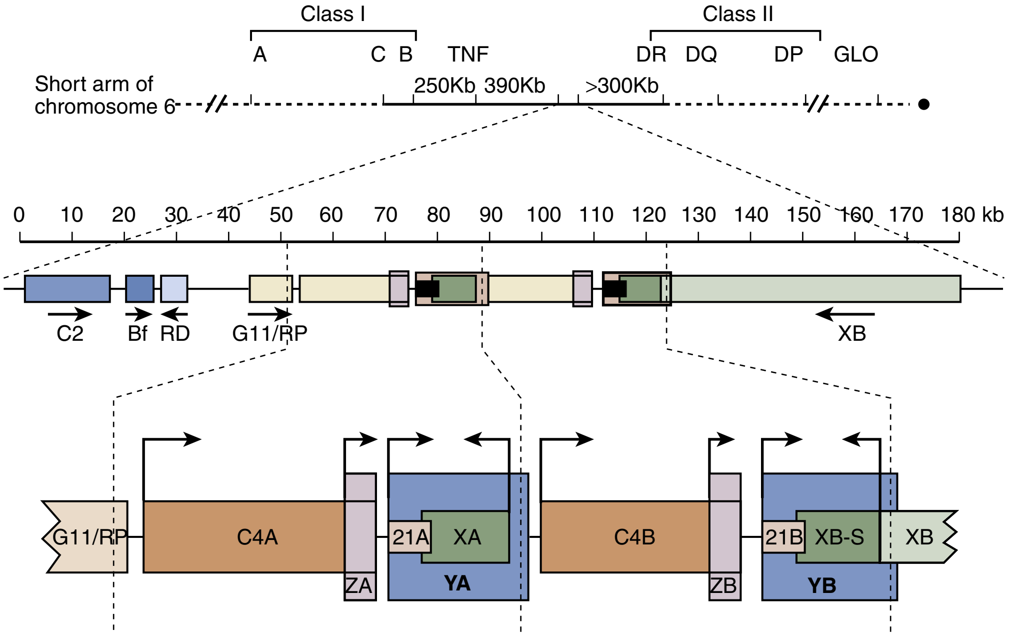

Figure 87.4 Genetic map of the human leukocyte antigen (HLA) locus containing the genes for P450c21. The *top line* shows the chromosome 6p21.1 region, with the telomere to the left and the centromere to the right. Most HLA genes are found in the class I and class II regions; the class III region containing the *CYP21* genes lies between these two. The *second line* shows the scale (in kb) for the diagram immediately below, showing *(from left to right)* the genes for complement factor C2, properdin factor Bf, and the RD and G11/RP genes of unknown function; *arrows* indicate transcriptional orientation. The *bottom line* shows the 21-hydroxylase locus on an expanded scale, including the *C4A* and *C4B* genes for the fourth component of complement, the *CYP21A1P* pseudogene (21A), and the active *CYP21A2* gene (21B) that encodes P450c21. XA, YA, and YB are adrenal-specific transcripts that lack open reading frames. The *TNXB* gene (XB) encodes the extracellular matrix protein tenascin-X; XB-S encodes a truncated adrenal-specific form of the tenascin-X protein whose function is unknown. ZA and ZB are adrenal-specific transcripts that arise within the C4 genes and have open reading frames, but it is not known if they are translated into protein; however, the promoter elements of these transcripts are essential components of the *CYP21A1P* and *CYP21A2* promoters. The *arrows* indicate transcriptional orientation. The *vertical dotted lines* designate the boundaries of the genetic duplication event that led to the presence of A and B regions.

The coding regions of the *CYP11B1* and *CYP11B2* genes share 93% amino acid identity and the same exonic gene structure found in all mitochondrial P450 genes. Despite the sequence similarities of these tandem genes, located within 40 kb on chromosome 8q24.3, the expression of P450c11AS is restricted to the adrenal zona glomerulosa, whereas P450c11β is found in the zona fasciculata and zona reticularis, emphasizing activity of zona-specific gene promoters. The regulation of P450c11β is driven mainly by cAMP in response to ACTH, whereas P450c11AS expression derives from potassium and angiotensin II activation of the protein kinase C pathway.[88] Thus, under normal circumstances, 18-hydroxylase and 18-oxidase activities are restricted to the zona glomerulosa, where 17-hydroxylase activity is low, limiting the repertoire of steroids that can undergo 18-oxygenation.

Although the organization of two highly homologous adjacent *CYP11B1* and *CYP11B2* genes on chromosome 8 is reminiscent of the *CYP21A1P* and *CYP21A2* genes, gene conversion in the *CYP11B* locus occurs rarely. Glucocorticoid-remediable aldosteronism (GRA) arises, however, when an unequal crossing over of the *CYP11B1* and *CYP11B2* genes creates a third, hybrid gene in which the ACTH-regulated promoter of *CYP11B1* drives expression of a chimeric protein with aldosterone synthase activity.[89] As a result, 18-hydroxylase and 18-oxidase activities are ectopically expressed in the zona fasciculata, leading to elevated renin-independent production of aldosterone, as well as 18-oxygenated metabolites of cortisol. The expression of this gene is suppressed by blunting ACTH production with glucocorticoids such as dexamethasone, which is used for diagnosis and treatment.[90]

The genetics of GRA has assisted in the precise identification of residues in P450c11AS that enable 18-oxygenase activities: residues 288, 296, 301, 302, 325, and, perhaps most importantly, 320 are critical for 18-oxygenase activities.[91,92] Therefore, crossovers 3′ to codon 320 do not enable aldosterone synthase activity. These key residues lie in or near the I-helix, which contains the catalytically important threonine residue implicated in oxygen activation for almost all P450s; thus, these mutations would be expected to alter active site geometry.

The x-ray crystal structure of modified human P450c11AS with bound DOC reveals the β-face of the steroid nucleus facing the heme iron, which enables oxygenation at C-11β, to form corticosterone, and subsequently at C-18, to form 18-hydroxycorticosterone and aldosterone.[93] In the x-ray crystal structure of P450c11AS with the inhibitor fadrozole bound to the active-site heme, the cyanophenyl ring of the *R*-fadrozole enantiomer forms hydrophobic interactions with the I-helix.[93] In the corresponding structure of the P450c11β-fadrozole complex, *S*-fadrozole adopts an opposite orientation pointed away from the I-helix.[94] The marked and unexpected differences for these two enzymes may contribute to their catalytic differences and enable the design of selective inhibitors. Osilodrostat, which is structurally related to *R*-fadrozole, potently inhibits both P450c11β and P450c11AS and is approved for the treatment of Cushing disease in the United States and Europe.[95] The activity of osilodrostat inhibiting P450c11β, and so lowering circulating cortisol levels, precluded its clinical development as an antihypertensive agent acting to reduce aldosterone secretion by inhibiting P450c11AS. Compounds that selectively inhibit P450c11AS but not P450c11β have begun to appear[96] and are being advanced into clinical trials.

In addition to 21-carbon steroids, both P450c11β and P450c11AS efficiently 11β-hydroxylate 19-carbon steroids, including androstenedione and testosterone.[93] In adrenal vein effluent, 11β-hydroxyandrostenedione is the third most abundant steroid after DHEAS and cortisol and is stimulated by ACTH.[97] In peripheral tissues, 11β-hydroxyandrostenedione is metabolized to 11-ketotestosterone, which is nearly as potent an agonist of the human androgen receptor as testosterone[98] and a dominant androgen in teleost fish and some reptiles. Accumulating evidence has demonstrated important contributions of these 11-oxygenated androgens to human physiology and disease[99] (see Pathways to 11-Oxygenated Androgens later).

KEY POINTS

- Expression of P450c11AS is restricted to the adrenal zona glomerulosa, whereas P450c11β is found in the zona fasciculata and zona reticularis.
- Regulation of P450c11β is driven mainly by cyclic adenosine monophosphate in response to adrenocorticotropic hormone (ACTH), whereas P450c11AS expression derives from potassium and angiotensin II activation of the protein kinase C pathway.
- Glucocorticoid-remediable aldosteronism arises from an unequal crossing over of the *CYP11B1* and *CYP11B2* genes to creates a hybrid gene in which the ACTH-regulated promoter of *CYP11B1* drives expression of a chimeric protein with aldosterone synthase activity.

P450aro (Aromatase)

The oxidative demethylation of C19 steroids, mainly androstenedione and testosterone, consumes three equivalents of molecular oxygen and NADPH, yielding formic acid and C18 steroids with an aromatic A-ring; hence the common name for this enzyme, *aromatase*. As is the case for P450scc, each subsequent oxygenation proceeds with greater efficiency with a distributive mechanism,[100] aiding in the completion of this transformation that is essential for estrogen biosynthesis in all animals.[26] The mechanism of this aromatization must account for the incorporation of the final oxygen atom from molecular oxygen into the formic acid by-product. The data are consistent with hydroxylation at C2 of 19-oxo-androstenedione via the iron oxene,[101] followed by an enzyme-assisted rearrangement and tautomerization of the intermediate dienone to the phenolic A-ring.[101] The x-ray structure of human aromatase with bound androstenedione supports this model, showing the steroid positioned with the β-face, C-19 methyl group, and A-ring adjacent to the heme iron.[102] Because all estrogen synthesis requires aromatase activity, the potent aromatase inhibitors letrozole, anastrozole, and exemestane are now first-line treatment for metastatic estrogen receptor-positive breast cancer in postmenopausal women.

P450aro is expressed in steroidogenic tissues (ovarian granuloma cells, placenta), in brain, and in nonsteroidogenic tissues, especially fat and bone.[26] The *CYP19A1* gene for P450aro spans over 75 kb (Table 87.2) and contains five different transcriptional start sites[26] with individual promoters that permit the tissue-specific regulation of expression in diverse tissues. P450aro is a glycoprotein, but glycosylation *per se* does not appear to affect activity.

Studies of patients with aromatase deficiency confirm that biologically significant estrogen synthesis derives entirely from this enzyme.[103] In fetuses homozygous for aromatase deficiency, the principal manifestation results from its deficiency in the placenta,[103] because ovarian steroidogenesis is quiescent during fetal life. Although huge amounts of estriol and estradiol are produced by the fetoplacental unit, estrogens are not needed for fetal development, the maintenance of pregnancy, or the onset of parturition; all of these processes proceed normally in fetuses lacking StAR, P450c17, or aromatase, or even in fetuses wholly lacking adrenal because of mutations in *SF-1* or *DAX-1*. However, in the absence of placental aromatase activity, androgenic C19 steroids derived from the fetal adrenal are passed into the maternal circulation, causing marked virilization of the mother.[103]

Furthermore, in pregnancies in which the mother has poorly treated 21-hydroxylase deficiency, maternal testosterone values can exceed 300 ng/dL (a midpubertal value for males), yet the fetus is not virilized,[104] because the maternal testosterone is efficiently metabolized to estradiol by placental aromatase. Thus, placental aromatase is a key enzyme in protecting both the fetus and mother from unwanted androgen exposure. After birth, individuals with aromatase deficiency grow normally and continue linear growth after completion of puberty, with males producing normal amounts of testosterone. However, when treated with estrogens, aromatase-deficient subjects fuse their epiphyses and cease linear growth.[105] These observations provide powerful evidence that bony maturation and epiphyseal fusion in children are mediated by estrogens, not androgens, even in males. These observations have led to the experimental use of aromatase inhibitors in various disorders of accelerated bone maturation.

REDOX PARTNER PROTEINS

The proteins collectively referred to as *redox partners* channel reducing equivalents from NADPH to the heme centers of P450 enzymes.[1] Many studies, however, suggest that these proteins promote catalysis by more than just their electron transfer properties. Because of this, the precise nature of the interactions of the P450s with their redox partners is of considerable importance.

Ferredoxin

Ferredoxin (FDX1) is encoded by a gene on chromosome 11q22 that spans over 30 kb. FDX1 is a small (14-kD), soluble Fe_2S_2 electron shuttle protein that resides either free in the mitochondrial matrix or is loosely bound to the inner mitochondrial membrane.[106] FDX1 is expressed in many tissues, and its expression in steroidogenic tissues is induced by cAMP in parallel with P450scc.[107]

Bovine FDX1 consists of two domains,[108] a core region and an interaction domain. The core region contains residues 1 to 55 and 91 to end (bovine numbering), including the four cysteines whose sulfur atoms tether the Fe_2S_2 cluster to the protein. Residues 56 to 90 form the interaction domain, which is a hairpin containing a helix at its periphery that includes acidic residues critical for the interaction of FDX1 with P450scc,[109] including aspartates 72, 76, and 79, plus glutamate 73). Similarly, the carboxylate group of D76 in FDX1 is cross-linked *in vitro* with lysine amino groups substituted for R370 or R366 of P450c11β and P450c11AS, respectively,[110] which is consistent with direct electrostatic pairings. A hydrophobic interaction with the adjacent L80 of FDX1 is also critical for binding and catalysis.[110] The Fe_2S_2 cluster lies in a protuberance in the molecule at the junction of its two domains. The charged residues of FDX1 cluster in the interaction domain, giving the molecule a highly negatively charged surface above the Fe_2S_2 cluster (see Fig. 87.3A). This description of the FDX1 molecule concurs with earlier studies that showed that overlapping sets of negative charges on FDX1 drive its interactions with positive charges on both P450scc and FDXR, which reduces oxidized FDX1. Because a preponderance of the evidence favors a model in which the same surface of FDX1 shuttles between FDXR and the P450 to transport electrons,[110,111] a model of how FDX1 interacts with FDXR should suggest how mitochondrial P450s interact with FDX1.

Ferredoxin Reductase

Like FDX1, ferredoxin reductase is widely expressed in human tissues, but its expression is two orders of magnitude higher in steroidogenic tissues.[112] The primary RNA transcript from the 11-kb *FDXR* gene (Table 87.2) on chromosome 17q24-q25 is alternatively spliced, generating two mRNA species that differ by only 18 bp, but only the protein encoded by the shorter mRNA is active in steroidogenesis.[113] Unlike most steroidogenic genes, the promoter for FDXR contains six copies of GGGCGGG sequences, which is the canonical binding site for the transcription factor SP-1 typically found in "housekeeping" genes. Accordingly, cAMP does not regulate transcription of the *FDXR* gene, as is the case for FDX1 and P450scc,[112] implying that FDXR plays additional roles in human physiology beyond steroidogenesis. Given their essential roles in the conversion of cholesterol to pregnenolone, no null mutations in FDXR or FDX1 have been described in humans.

Bovine FDXR also consists of two domains, each comprising a β-sheet core surrounded by α-helices.[114] The NADP(H)-binding domain is a compact region composed of residues 106 to 331 (bovine numbering), whereas the more open FAD domain, formed by the remaining N- and C-terminal residues, binds the dinucleotide portion of FAD across a Rossman fold with the redox-active flavin isoalloxazine ring abutting the NADP(H) domain. By analogy to related structures including glutathione and thioredoxin reductases, the nicotinamide ring of NADPH is modeled to lie adjacent to the flavin ring in position to transfer its two electrons to the FAD. Thus, intramolecular electron transfer occurs in the cleft formed by the angled apposition of these two domains. Within this cleft, basic residues abound, including arginines 240 and 244, which are important for interactions with FDX1.[113] Hypothetical docking of the two structures suggests that the negative surface of FDX1 fits elegantly into the positive surface of FDXR, even with NADP(H) bound.[114] These studies illustrate the similarities in the electrostatic interactions of FDX1 with both FDXR and the mitochondrial P450s.

P450 Oxidoreductase

The flavoprotein POR is expressed widely in human tissues and serves as the sole electron-transfer protein for all microsomal P450s, including xenobiotic-metabolizing hepatic P450s, steroidogenic P450s, and P450s found in other tissues such as the kidney and brain.[115] Crystallographic studies show that POR contains two lobes, one binding FAD and the other binding FMN, and a flexible N-terminus that tethers it to the endoplasmic reticulum.[116] NADPH is bound to the cofactor-binding domain above the FAD in a β-sheet–rich FAD domain, and an α-helical connecting domain joins the FAD and the FMN domains. A disordered "hinge" of approximately 25 residues lies between the FMN domain and the connecting domain, suggesting that the FMN and FAD domains can move substantially relative to each other. In the x-ray structure of rat liver POR, the FMN and FAD lie at the base of a cleft formed by the butterfly-shaped apposition of the FAD and FMN domains, reminiscent of the electron transfer surface of FDXR.[114] Nuclear magnetic resonance (NMR) and small-angle x-ray scattering studies[117] and ion mobility spectrometry confirm that, once the electrons reach the FMN domain, POR "opens up" via its hinge so that the FMN domain may dock with the redox-partner binding site of the P450 by electrostatic interactions (see Fig. 87.3). The surface of the electron-donating FMN domain is dominated by acidic residues, whereas the redox-partner binding site of P450 enzymes contain numerous basic residues. Negative charges of the FMN domain guide interactions with positive charges on the P450. The FMN approaches no closer than 18 Å from the heme, similar to the 16-Å distance of FAD from the Fe_2S_2 cluster in the modeled FDXR-FDX1 complex, and presumably similar to the distance of the heme from the Fe_2S_2 cluster in the P450-FDX1 complex.[114] These distances are too far for electrons to "jump" directly to the heme; rather, electron transfer apparently uses the polypeptide chain as a conduit.[118] Basic residues in the redox-partner-binding surface are crucial for interactions with POR and for electron transfer, and these positive charges in human P450c17 are critical for maximal 17,20-lyase activity.[61] Thus, these structures demonstrate several key principles of the electron transfer proteins involved in human steroidogenesis: NADPH and prosthetic groups lie at the interfaces of protein domains in which electron transfer occurs; the electron transfer surfaces are negatively charged to pair with positive charges on the P450s; the terminal electron transfer moiety (FMN domain or FDX1) must be mobile or soluble to pass electrons on to the P450; and electrons flow from the FMN or Fe_2S_2 cluster along the adjacent polypeptide chain to the heme.

Cytochrome P450 Oxidoreductase Deficiency: A Disorder Affecting Multiple P450 Enzymes. Beginning with a clinical report in 1985,[119] several patients have been described with clinical and hormonal findings, suggesting partial deficiencies of both P450c17 and P450c21. Some of these individuals were born to mothers who had become virilized during pregnancy, suggesting fetoplacental aromatase deficiency, and many also had the Antley–Bixler skeletal malformation syndrome characterized by craniosynostosis and radioulnar synostosis. Approximately half of patients with Antley–Bixler syndrome have normal steroidogenesis and normal genitalia; these subjects have dominant, gain-of-function mutations in the gene for fibroblast growth factor type 2 receptor (*FGFR2*); however, patients with Antley–Bixler syndrome who also have genital anomalies and disordered steroidogenesis do not have *FGFR2* mutations. The initial report described three patients with Antley–Bixler syndrome, genital ambiguity, and hormonal findings, suggesting partial deficiencies of 17α-hydroxylase and 21-hydroxylase, as well as a fourth patient who was phenotypically normal but had a similar hormonal profile; all had recessive, loss-of-function amino acid replacement mutations in POR.[120] One of these patients was born to a woman who had become virilized during the pregnancy, suggesting partial fetoplacental aromatase deficiency.

In vitro biochemical assays of the recombinant mutant POR proteins showed that the mutations in the Antley–Bixler subjects had severely impaired, but not totally absent, activity, whereas the mutations found in a phenotypically normal subject with amenorrhea were less severe.[120] Examination of the *POR* and *FGFR2* genes in a series of 32 patients established that the recessive *POR* mutations and the dominant *FGFR2* mutations segregate completely.[121] Approximately 100 POR-deficient patients have been described.[122] It appears unlikely that subjects will be found who are homozygous for null *POR* alleles, because knockouts of POR in mice cause embryonic lethality. POR is required for the activities of all hepatic drug-metabolizing P450 enzymes, and liver-specific ablation of the *Por* gene in mice results in phenotypically and reproductively normal animals with profoundly impaired drug metabolism.[123] Furthermore, the human *POR* mutations identified in patients interfere with *in vitro* drug metabolism by most hepatic P450 enzymes to varying degrees, and at least one report describes impaired metabolism of test drugs by a POR-deficient patient.[124] Consequently, it seems likely that some patients with POR deficiency may also metabolize drugs poorly.

The human *POR* gene, located on chromosome 7, consists of 16 exons (Table 87.2). The sequence of this gene in 842 normal persons from four ethnic groups revealed a high degree of polymorphism.[125] The coding sequence variant A503V, found on approximately 28% of all alleles, reduced the 17α-hydroxylase and 17,20-lyase activities of P450c17 to approximately 60% of normal[121,125] and some, but not all drug metabolism by CYP3A4 and CYP2D6, but had no measurable effect on the activities of P450c21 or hepatic CYP1A2 or CYP2C19. The POR promoter polymorphism –152C→A, found on 13% of Caucasian alleles, reduced *POR* gene transcription by about half in both adrenal and liver cells in culture, but the potential clinical significance of this is unknown.

Cytochrome b5

The small (12- to 17-kD) hemoprotein cytochrome b5 (CYB5A, b5) is found in two forms: the full-length protein is membrane-bound in the liver, and a soluble form lacking the C-terminal membrane anchor is found in erythrocytes. Full-length cytochrome b5 is expressed in both the adrenal and the gonads, where it can interact with P450c17; the adrenal expression is largely confined to the zona reticularis and may contribute to the genesis of adrenarche.[54] While cytochrome b5 appears to transfer the second electron for some P450 reactions,[126] apo-b5, which does not transfer electrons, also stimulates the 17,20-lyase activity of human P450c17.[39] These experiments suggest that cytochrome b5 does not act alone as an electron donor, but rather functions in concert with POR to somehow aid catalysis, yet b5 might substitute for POR in other P450 systems.

The soluble form of bovine b5 was one of the first proteins studied by x-ray crystallography, and a wealth of structural data for b5 have been acquired using molecular dynamics and NMR spectroscopy for both the holo- and apo-b5.[127,128] Analogous to FDX1, b5 consists of two domains, a heme-liganding core 1 domain (residues 40 to 65, bovine numbering); and a structural core 2 domain, from which the C-terminal membrane-anchoring helix extends. The heme extends more to the periphery of cytochrome b5 than does the Fe_2S_2 cluster of FDX1, and the entire surface is dominated by negatively charged residues rather than just one cluster of negative charges near the heme. In addition, the core 1 domain acquires considerable conformational flexibility in apo-b5, whereas the core 2 domain remains folded as in holo-b5.[127] Finally, the C-terminal membrane-spanning helix (exiting the core 2 domain) is required to stimulate the 17,20-lyase activity of human P450c17, but the signal peptide is not.[129] Genetic and biochemical studies have implicated basic residues in P450c17, including R347, R358, R449, and K89, as important for its interaction with cytochrome b5,[59,129,130] while E48 and E49 of cytochrome b5 are required for high 17,20-lyase activity.[131] The major effect of cytochrome b5 on the P450c17-POR complex to augment 17,20-lyase activity is to increase the coupling of electron transfer to product formation, from 5% to almost 50%.[62]

KEY POINTS

- Redox partner proteins play and essential role in transferring reducing equivalents from nicotinamide adenine dinucleotide phosphate to the heme centers of P450 enzymes.
- Ferredoxin reductase contains one flavin prosthetic group and transfers electrons to the iron-sulfur protein ferredoxin, the ultimate electron-transfer protein to the mitochondrial P450 enzymes.
- P450-oxidoreductase (POR) contains two flavins and is the sole electron-transfer protein for all microsomal P450 enzymes; mutations in POR impair multiple P450 activities.
- Cytochrome b5 augments the 17,20-lyase activity of the P450c17-POR complex.

STEROIDOGENIC DEHYDROGENASES AND REDUCTASES

3β-Hydroxysteroid Dehydrogenase/$\Delta^5\rightarrow\Delta^4$-Isomerases

Conversion of Δ^5 steroids into their Δ^4 congeners, a step required for the production of progestins, mineralocorticoids, glucocorticoids, and sex steroids, consists of two chemical transformations, both performed by the 3β-hydroxysteroid dehydrogenase/$\Delta^5\rightarrow\Delta^4$-isomerase (3βHSD) enzymes. The first reaction is the oxidation of the 3β-hydroxyl group to the ketone, and during this process NAD^+ is converted to NADH. The intermediate Δ^5-3-ketosteroid remains tightly bound to the enzyme with nascent NADH, and the presence of NADH in the cofactor-binding site activates the enzyme's second activity, the $\Delta^5\rightarrow\Delta^4$-isomerase activity.[132] Competition experiments have shown that the dehydrogenase and isomerase activities reside in a single active site,[133] yet these enzymes are often referred to by their dehydrogenase activity alone.

Although rodents contain multiple 3βHSD isoforms, human beings have only two active genes. The type 1 enzyme (3βHSD1) is expressed in the placenta, liver, brain, and some other tissues.[134] This isoform is required for placental progesterone production during pregnancy, which may explain why a deficiency of 3βHSD1 has never been described. In contrast, the type 2 enzyme (3βHSD2) is by far the principal isoform in the adrenal glands and the gonads.[135] Deficiency of 3βHSD2 causes the rare form of congenital adrenal hyperplasia known as *3βHSD deficiency*.[46] The presence of the type 1 isozyme in these patients helps to explain the paradox of why 46,XX individuals born with severe 3βHSD2 deficiency can virilize slightly *in utero* and can have elevated 17-hydroxyprogesterone (17OHP) in newborn screening tests. The 3βHSD block in the adrenal gland diverts Δ^5-steroids away from cortisol and toward DHEA; extraadrenal 3βHSD1 enables 17OHP and testosterone synthesis despite absent 3βHSD2 in the adrenal. The N367T allele of 3βHSD1 is variably present in all populations, and this variant has equivalent catalytic activity as wild-type 3βHSD1; however, the N-to-T substitution disrupts a ubiquitination site. In prostate cancer cells, the 367T allele is resistant to degradation and provides a selective advantage by maintaining the 3βHSD activity required to form active androgens from DHEA.[136]

The types 1 and 2 enzymes share 93.5% amino acid identity, and all biochemical studies comparing the two enzymes yield very similar results. The enzymes are strongly inhibited by Δ^4 products[137] and by synthetic Δ^4 steroids such as medroxyprogesterone acetate and the 3-keto-Δ^4-metabolite of abiraterone.[138] Compared to the type 1 enzyme, the type 2 enzyme is higher affinity/lower capacity (lower K_m, and V_{max}) and thus efficiently converts Δ^5 steroids pregnenolone, 17α-hydroxypregnenolone, DHEA, and androst-5-ene-3β,17β-diol to their Δ^4 congeners in the adrenals and gonads.[133] The enzymes are primarily membrane-bound and are found both in the microsomal and mitochondrial fractions during subcellular fractionation.[133]

Considerable evidence suggests that 3βHSD activity is an important factor in regulating adrenal production of DHEAS. The human fetal adrenal, which produces vast amounts of DHEAS, contains little 3βHSD immunoreactivity.[139] Furthermore, the expression of 3βHSD in the innermost regions of the adrenal cortex declines as the zona reticularis develops in childhood, and 3βHSD immunoreactivity is low in the zona reticularis of the adult rhesus macaque and of humans.[54] Thus, the development of an adrenal cell type (reticularis) that is relatively deficient in 3βHSD activity is a necessary component of adrenarche, in which adrenal production of the Δ^5 steroids DHEA and DHEAS rises exponentially.[140]

17β-Hydroxysteroid Dehydrogenases

There are at least 14 human 17β-hydroxysteroid dehydrogenase (17βHSD) isoforms; these isoforms vary widely in size, structure, substrate specificity, cofactor utilization, and physiologic functions.[141] This section focuses on the human isoforms that possess significant, rather than gratuitous, 17βHSD activity.

17β-Hydroxysteroid Dehydrogenase Type 1. In the late 1980s, three independent groups reported the cloning of 17βHSD1 cDNA, the first of any human HSD.[142] Located on chromosome 17q25 adjacent to a pseudogene, the *HSD17B1* gene (Table 87.2) encodes a 34-kD protein subunit that is expressed primarily in the placenta and in ovarian granulosa cells of developing follicles.[141] The enzyme, which is active only as a dimer, accepts mainly estrogens such as estrone, although it also has low catalytic activity for the conversion of androstenedione to testosterone and DHEA to androst-5-ene-3β,17β-diol.[143] Although the enzyme can oxidize 17β-hydroxysteroids in the presence of NAD+ *in vitro* at a high pH, the enzyme functions *in vivo* to reduce estrone to estradiol and 16α-hydroxyestrone to estriol.[143]

Sequence alignments with other members of the SDR family identified a Y-X-X-X-K active-site motif in residues 155 to 159, which was confirmed crystallographically.[144] The structure demonstrates that cofactor lies across the β-sheet core of the protein in a Rossman fold characteristic of all SDR enzymes. Steroid appears to dangle from the top of the enzyme almost perpendicular to the cofactor, with a hydrophobic pocket holding the body of the steroid in place while the 3-hydroxyl forms hydrogen bonds with H221 and E282. At the place where the steroid and cofactor meet, S142, Y155, and K159 help to form a proton-relay system that drives catalysis.

Because steroid flux to estrogens preferentially occurs via the aromatization of androstenedione to estrone, 17βHSD1 appears to be required for the conversion of estrone to biologically active estradiol in the ovary and placenta. This role has not been proven unequivocally, because no cases of human 17βHSD1 deficiency have been reported, although female mice with targeted disruption of the *Hsd17b1* gene show reduced fertility.[145] Such a disease is theoretically compatible with life, because fetuses with aromatase deficiency[103] and estrogen insensitivity (ERα mutations) are viable. Nevertheless, this enzyme is probably critical for ovulation and may be important in the pathogenesis and progression of estrogen-dependent breast cancers.[146]

17β-Hydroxysteroid Dehydrogenase Type 2. In contrast to the "activating" role of 17βHSD1 in the placenta and ovary, human endometrium inactivates estradiol by the conversion to estrone. The 17βHSD1 mRNA is not detected in the human uterus, but a related cDNA encoding microsomal *HSD17B2* was cloned[147] and found to be expressed in endometrium, placenta, and other tissues.[148] 17βHSD2 converts estradiol to estrone and oxidizes testosterone and DHT to their inactive 17-ketosteroid homologs androstenedione and 5α-androstanedione, respectively. The widespread tissue distribution and broad substrate specificity of 17βHSD2 suggests that its role in human physiology is to protect tissues from excessive exposure to active steroid hormones by oxidation to inactive 17-ketosteroids.[141] Human deficiency of this most active human inactivating (oxidizing) 17βHSD has not been described, but targeted disruption of the mouse *Hsd17b2* gene results in placental defects and embryonic lethality,[149] which suggests a broad and fundamental importance of this isoenzyme. The type 2 enzyme also oxidizes 20α-dihydroprogesterone to progesterone, but this activity is low relative to its 17βHSD activity.[147]

17β-Hydroxysteroid Dehydrogenase Type 3. A form of 46,XY disordered sex development (DSD) lacking the enzyme capable of reducing androstenedione to testosterone, was reported in the 1970s.[150] When the large, complex *HSD17B3* gene encoding 17βHSD3 was cloned, patients with the androgenic "17-ketosteroid reductase deficiency" were found to harbor mutations in this gene,[151,152] proving the central role of this enzyme in male sexual differentiation and marking 17βHSD3 as the only 17βHSD enzyme whose role in human physiology is genetically established by a deficiency syndrome. Nonetheless, patients with 17βHSD3 deficiency produce enough testosterone to virilize incompletely at puberty, suggesting that one or more additional human 17βHSD enzymes convert androstenedione to testosterone (see later). Similarly, the human ovary exports some testosterone despite an absence of 17βHSD3 expression, and women with 17βHSD3 deficiency produce normal amounts of androgens and estrogens.[153]

Unlike 17βHSD1, which has been the subject of intense biochemical study, relatively little is known about 17βHSD3 enzymology. This knowledge gap is at least in part caused by the very hydrophobic nature of the encoded 310-amino acid protein, hampering the expression of this enzyme in bacteria. From experiments in transiently transfected HEK-293 cells, 17βHSD3 reduces all of the C19 17-ketosteroids that serve as precursors of testosterone and DHT in human beings, including DHEA, 5α-androstanedione, and androsterone.[152] The conversion of DHEA to androst-5-ene-3β,17β-diol by 17βHSD3 probably contributes significantly to testicular testosterone synthesis. Estrogens such as estrone are poor substrates for human 17βHSD3.[143]

17β-Hydroxysteroid Dehydrogenase Type 4. Many additional HSD isoforms have been described in rodents and in humans, but the activities of these isoforms for steroids are generally poor. For example, the type 4 enzyme is a trifunctional protein located in peroxisomes, but its (oxidative) HSD activity toward estradiol is 106 times slower than its 3-hydroxyacyl-coenzyme A dehydrogenase activity.[154] Deficiency of the type 4 enzyme causes Zellweger syndrome, in which bile acid synthesis is disturbed but steroidogenesis is not affected. Thus, this enzyme has 17βHSD activity as one of its repertoire of transformations, but steroidogenesis is not its principal physiologic function.

17β-Hydroxysteroid Dehydrogenase Type 5 (Aldo-Keto Reductase Family 1 Member C3). Unlike 17βHSD types 1 to 4, which are SDR enzymes, the type 5 enzyme (AKR1C3) is an AKR enzyme that is expressed both in steroidogenic and nonsteroidogenic tissues.[155] Originally described as hepatic 3αHSD type 2 for its ability to reduce DHT to 5α-androstane-3α,17β-diol, this protein was later found also to have 17βHSD activity.[155] This enzyme, now known as AKR1C3 (see 3α-HSDs), may account for much of the extratesticular androstenedione-to-testosterone conversion, although its catalytic efficiency as a 17βHSD is poor[156] compared with its 20α-HSD activity with progesterone and DOC or its prostaglandin dehydrogenase activity, reducing PGH2 to PGF2α. Nevertheless, AKR1C3 is more highly expressed in the human fetal adrenal during the time of sexual differentiation than 17βHSD3[44] and may participate in androgen production, particularly in virilizing congenital adrenal hyperplasias. The postnatal adrenal also expresses low levels of AKR1C3, accounting for the small amount of testosterone secreted directly by the adrenal.[157]

17β-Hydroxysteroid Dehydrogenase Type 6. This enzyme is discussed under the 3α-hydroxysteroid dehydrogenases below.

Steroid 5α-Reductases

The conversion of testosterone to DHT in target tissues was described in the 1960s,[158] and studies using fibroblasts suggested that at least two human enzymes with different pH optima and genetics performed these transformations.[159] These initial results were confirmed when the genes encoding the type 1 and type 2 enzymes were cloned, and patients with clinical 5α-reductase deficiency were found to have deletions or mutations in the *SRD5A2* gene.[160] The two isoforms are very hydrophobic 30-kD microsomal proteins that share 50% identity. The type 1 enzyme is expressed in adult nongenital skin and liver and is not expressed significantly in fetal peripheral tissues, but the enzyme is expressed in the fetal testis and fetal adrenal very early in gestation.[44] Consequently, deficiency of the type 2 enzyme is not compensated for by the type 1 enzyme in the fetus.[161] The type 2 enzyme remains the predominant enzyme in genital skin, male accessory sex glands, and prostate, whereas the type 1 enzyme accounts for most of the hepatic 5α-reduction.

Although 5α-reductase activity is generally discussed in the context of male genital differentiation and androgen action, both isozymes reduce a variety of steroids in what are believed to be degradative pathways in humans. Progesterone, 17OHP, and related C21 steroids are the best substrates for both 5α-reductases, particularly the type 1, and cortisol, cortisone, corticosterone, and related compounds are also good substrates.[162] The 5α- (and 5β-) reduced steroids may be metabolized further and conjugated for excretion in the urine. Given the importance of 5α-reductase type 2 in prostate growth, inhibitors of the type 2 enzyme have been developed for the treatment of prostatic hyperplasia and the prevention of its recurrence after surgery. Finasteride selectively inhibits human 5α-reductase type 2, whereas dutasteride inhibits both the type 1 and type 2 isoenzymes. Both drugs are approved for treatment of prostatic hyperplasia in the United States.

Although the function of 5α-reductase type 2 is firmly established from the studies of its deficiency, which is a form of 46,XY DSD, the role of the type 1 isoform in humans is less clear, but its expression in the fetal adrenal and testis and the now-established role of the backdoor pathway in human male sexual development suggest that the type 1 enzyme might participate in normal and abnormal sexual development. Furthermore, the type 1 isoenzyme appears to be the dominant 5α-reductase expressed in most prostate cancers and thus controls the pathways of precursor flux to DHT.[163] Given the abundant expression of the type 1 isoform in liver, and its high activity with C21 steroids, this enzyme has been ascribed a role of degrading circulating C21 steroids in preparation for excretion in the urine. However, disruption of the *Srd5a1* gene in mice results in delayed parturition, a defect that can be rescued with 5α-androstane-3α,17β-diol. In immature mice, 5α-reductase type 1 is expressed both in the ovary and in the Leydig cells, and this enzyme participates in the testicular synthesis of 5α-androstane-3α,17β-diol via two pathways.[164] Whether 5α-reductases are expressed in postnatal human adrenal or gonads in normal physiology or in pathologic states is not known.

3α-Hydroxysteroid Dehydrogenases

The four major human 3α-hydroxysteroid dehydrogenases (3αHSDs) are AKR enzymes with reductive preferences that belong to the AKR1C family (AKR1C1, 2, 3, and 4). The 3αHSDs types 1, 2, 3, and 4 are trivial names for AKR1C4, 1C3, 1C2, and 1C1, respectively, which are clustered on chromosome 10p14-p15. Each enzyme has its characteristic tissue distribution[165] and repertoire of catalytic activities.[2,156] AKR1C3 also performs the 17βHSD reaction with androstenedione and is known also as 17βHSD5, and all of these AKR1C isoforms catalyze additional reactions, such as the 20α-reduction of pregnanes. In the brain, 3αHSDs reduce 5α-dihydroprogesterone to tetrahydroprogesterone (allopregnanolone), which is an allosteric activator of the GABA_A receptor-chloride channel complex with a nanomolar affinity[166] and is approved for the treatment of postpartum depression in the United States.[167] AKR1C4 is abundant in liver but has been found in adrenal and gonad; AKR1C3 was cloned from liver, prostate, and brain; AKR1C2 is found in the prostate and brain; and AKR1C1 is abundant in the uterus. The amino acid sequences of the type 2 and 3 isoenzymes differ by only a few residues and have common allelic variations. These minor differences in sequences, however, cannot be neglected, because these differences might alter substrate utilization.

In the central nervous system, selective serotonin reuptake inhibitors (e.g., the antidepressant drugs fluoxetine and paroxetine) directly lower the *K*m of rat brain type 2 3αHSD for 5α-dihydroprogesterone by almost 10-fold,[168] which explains why these drugs augment brain allopregnanolone concentrations, perhaps contributing to their antidepressant activity. In addition, x-ray crystallography has shown that the β subunit of the mammalian voltage-gated potassium channel is a tetrameric structure[169] in which each subunit closely resembles the rat liver 3αHSD (AKR1C9)[170] and even contains bound NADP^+ with high occupancy. Although the broader implications of this work are not yet known, these studies suggest a role of HSDs in coupling intracellular redox state to membrane excitation.

The 3αHSDs differ from the 11βHSDs, 3βHSDs, and 17βHSDs types 1 through 4 in several respects, because all reductive 3αHSDs are AKR enzymes rather than SDR enzymes.[2] As AKR enzymes, they function as monomers with a TIM-barrel structure; they bind cofactor with the nicotinamide ring draped across the mouth of the “barrel” rather than lying on a Rossman fold; and their kinetic mechanisms are highly ordered, with cofactor dissociation the final and rate-limiting step.[171] Tight NADP(H) binding derives from interaction of R276 with the 2′-phosphate, and mutation of R276 eliminates a conformational change associated with tight binding[172] and attenuates or reverses the preference for ketosteroid reduction in intact cells.[3] As shown in the structure of AKR1C9,[170] their active sites also contain tyrosine and lysine residues to facilitate proton transfer during catalysis, but these residues are distantly located in linear sequence rather than confined to the Y-X-X-X-K motif as in SDR enzymes.

In contrast to the reductive 3αHSDs, the oxidative 3αHSDs belong to the SDR family and show greatest similarity to the retinol dehydrogenase or cis-retinol/androgen dehydrogenase (RoDH/CRAD) subfamily.[173] Although several of these RoDH/CRAD enzymes show some 3αHSD activity, the most active enzyme has been called RoDH, the microsomal 3αHSD, 3(α→β)-hydroxysteroid epimerase, or formally 17βHSD6, whose *HSD17B6* cDNA was first cloned from prostate.[174] This enzyme converts the inactive C19 steroid 5α-androstane-3α,17β-diol to DHT, and thus likely catalyzes the final step in the backdoor pathway from 17OHP to DHT via androsterone.[44] Prolonged incubation of 3α-hydroxysteroids with cells transfected with the cDNA for 17βHSD6 or with microsomes containing the recombinant enzyme, however, yields subsequent 3-ketosteroid metabolites, including both 3α- and 3β-hydroxysteroids and 17β-hydroxysteroids.[175] Hence, this enzyme has complex catalytic flexibility, and may serve a variety of biological functions.

11β-Hydroxysteroid Dehydrogenases

The 11β-hydroxysteroid dehydrogenases (11βHSD) regulate the bioactivity of endogenous and synthetic glucocorticoids, and a comparison of the types 1 and 2 enzymes exemplifies some key principles of HSD enzymology (Table 87.3). Both enzymes are hydrophobic, membrane-bound proteins that bind cortisol/cortisone and corticosterone/11-dehydrocorticosterone, but otherwise their properties and physiologic roles differ substantially[176] (see Table 87.3). The type 2 enzyme shares only 21% sequence identity with 11βHSD1, whereas 11βHSD2 and 17βHSD2 share 37% identity and favor steroid oxidation *in vivo*. Thus, 11βHSD1 and 11βHSD2 are only distantly related members of the SDR family, yet they perform opposite functions in specific tissues in human physiology and pharmacology.

TABLE 87.3 Comparison of 11β-Hydroxysteroid Dehydrogenases Types 1 and 2

Property	Type 1	Type 2
Size	34 kD	41 kD
Orientation in ER	Luminal	Cytoplasmic
Expression	Liver, decidua, lung, gonad, pituitary, brain, fat, bone	Kidney, placenta, colon, salivary gland
Principal reaction	Reduction	Oxidation
Cofactor preference	NADPH via H6PDH	Cytoplasmic NAD^+
Substrate binding	Low affinity (K_m 0.2-2 μM)	High affinity (K_m 0.01-0.1 μM)
Inhibition by carbenoxolone	Moderate	Strong
Deficiency state	CRD (H6PDH > HSD11B1)	AME

ER, Endoplasmic reticulum; *NADPH,* nicotinamide adenine dinucleotide phosphate, reduced form; *NAD+*, nicotinamide adenine dinucleotide, oxidized form; *H6PDH,* hexose-6-phosphate dehydrogenase; *CRD,* cortisone reductase deficiency; *AME,* apparent mineralocorticoid excess.

The 34-kD type 1 enzyme (11βHSD1) is expressed in the liver, testis, lung, fat, and proximal convoluted tubule.[177] The type 1 enzyme catalyzes both the oxidation of cortisol using $NADP^+$ as a cofactor (Km 1–2 μM) and the reduction of cortisone using NADPH as a cofactor (Km 0.1–0.3 μM), with cortisone reduction being the dominant reaction in transfected cells.[176] Some synthetic glucocorticoids such as prednisone are 11-ketosteroids that must be reduced to their 11β-hydroxy derivatives to attain biologic activity, and these transformations are performed mainly in the liver by 11βHSD1. In contrast, when recombinant 11βHSD1 is studied *in vitro*, cortisol oxidation with $NADP^+$ is most efficient, and cortisone reduction is only achieved if $NADP^+$ is scrupulously removed with an enzymatic NADPH regeneration system.[178] Thus, the net flux of steroid driven by 11βHSD1 depends on the relative concentrations of available NADPH and $NADP^+$, which usually favors reduction in cells, especially given the high Km of the enzyme for cortisol.[178]

The mechanism for the discrepancy between the prominent oxidative preference *in vitro* and the reductive dominance *in vivo*, however, is more complex and derives from the localization of 11βHSD1 in the lumen of the endoplasmic reticulum.[179] In this compartment, the ratio of NADPH to $NADP^+$ is not maintained by the cytoplasmic $NADP^+$-coupled dehydrogenases (mainly glucose-6-phosphate dehydrogenase), but by hexose-6-phosphate dehydrogenase (H6PDH). Indeed, most patients with apparent cortisone reductase deficiency (CRD), which is characterized by high ratios of cortisone to cortisol and of their respective metabolites in blood and urine,[180] bear loss-of-function mutations in *H6PDH*[181] rather than *HSD11B1*. These mutations impair regeneration of the NADPH within the endoplasmic reticulum, which serves as cofactor for the 11βHSD1 reaction. The genetics and pathophysiology of CRD provide an excellent example of the critical role of nicotinamide cofactors in HSD function and biology and the molecular complexity of steroidogenesis.

In contrast, the 41-kD type 2 enzyme catalyzes the oxidation of cortisol and corticosterone using NAD^+, and, although this enzyme has a high affinity for its steroid substrates (K_m 0.01–0.1 μM),[182] catalysis of the reductive reactions by 11βHSD2 has not been conclusively demonstrated. In addition, 11βHSD2 also oxidizes 11β-hydroxyandrostenedione and 11β-testosterone to their 11-ketosteroids, as described in the 11-oxyandrogen pathway section later. Cortisol is a potent agonist at the mineralocorticoid (glucocorticoid type 2) receptor in the distal nephron, but its oxidized 11-keto derivative, cortisone, is not a mineralocorticoid. The reason cortisol does not act as a mineralocorticoid *in vivo*, even though cortisol concentrations can exceed aldosterone concentrations by three orders of magnitude, is because cortisol is enzymatically converted to cortisone in the cells lining the cortical and medullary collecting ducts. Thus, the type 2 enzyme inactivates the mineralocorticoid activity of cortisol in the kidney tubule,[183] and inactivating mutations in the type 2 enzyme cause a syndrome of apparent mineralocorticoid excess[184] (see Chapter 88). This enzyme system may be overwhelmed in cases of prodigious excess cortisol production, as seen in the ectopic ACTH syndrome, where cortisol acting at the mineralocorticoid receptor causes hypokalemia and hypertension. The presence of the type 2 enzyme in the placenta[182] also inactivates endogenous and synthetic corticosteroids such as prednisolone, allowing the use of these agents during pregnancy without affecting the fetus. In contrast, 9α-fluorinated steroids such as dexamethasone are minimally inactivated by the type 2 enzyme, primarily because of a shift in the oxidation/reduction preference rather than a reduction in affinity for the enzyme. It is this resistance to inactivation by placental 11βHSD2 that is essential for synthetic glucocorticoids to “cross the placenta” and to exert a pharmacologic effect on the fetus. Furthermore, the relatively high placental concentrations of $NADP^+$ may also favor the oxidative action of 11βHSD1, so that both placental enzymes protect the fetus from the high maternal concentrations of cortisol that occur during pregnancy.[176]

STEROID SULFONATION

The steroid sulfotransferase (SULT) enzymes are cytosolic enzymes that use 3′-phosphoadenine-5′-phosphosulfate (PAPS) as a sulfate donor. The SULT1E1 isoenzyme sulfonates the phenolic 3-hydroxyl group of estrogens, and the SULT2A1 isoenzyme sulfonates the Δ^5 steroids pregnenolone, 17-hydroxypregnenolone, androst-5-ene-3β, 17β-diol, and most importantly DHEA. SULT2A1 is abundant in the adrenal zona reticularis,[185] which efficiently converts most of the nascent DHEA to DHEAS. The sulfate donor PAPS derives from two molecules of ATP and sulfate, through the ATP sulfurylase and adenosine phosphosulfate (APS) kinases, the PAPS synthases types 1 and 2 (PAPSS1, PAPSS2). Whereas PAPSS1 is ubiquitously expressed, PAPSS2 expression is high in cartilage, adrenal, and liver. Loss-of-function mutations in PAPSS2 deplete the adrenal gland of PAPS and increase production of unconjugated DHEA. This circulating DHEA is a substrate for peripheral 3βHSD1, which yields adrenal-derived androgens. Rare cases of incomplete PAPSS2 deficiency have been described in girls with premature pubarche, advanced bone age, acne, hirsutism, and subsequent secondary amenorrhea.[186] These children have mild to moderate skeletal deformities, whereas complete PAPSS2 deficiency causes autosomal recessive brachylomia and severe bone disease, primarily affecting the spine.

KEY POINTS

- Conversion of Δ^5 steroids into their Δ^4 congeners, a step required for the production of progestins, mineralocorticoids, glucocorticoids, and sex steroids, consists of two chemical transformations, both performed by the 3β-hydroxysteroid dehydrogenase/$\Delta^5 \rightarrow \Delta^4$-isomerase enzymes.
- 17β-hydroxysteroid dehydrogenase isoforms play critical roles in the production and degradation of sex steroids.
- 3α-hydroxysteroid dehydrogenases are involved in the “backdoor pathway” to DHT.
- 11β-hydroxysteroid dehydrogenases catalyze the interconversion of cortisol/cortisone, and corticosterone/11-dehydrocorticosterone; 11βHSD2 also oxidizes 11β-hydroxyandrostenedione and 11β-testosterone to their 11-ketosteroids in the 11-oxyandrogen pathway.

PATHWAYS

Adrenal Steroidogenic Pathways

Diagrams of steroidogenic pathways, such as that shown in Fig. 87.2, typically combine the pathways from multiple cell types to give a comprehensive and inclusive illustration; however, such diagrams may be misleading, as dominant pathways by which specific steroids are synthesized differ in each steroidogenic cell type. The three major pathways of steroidogenesis in each zone of the human adrenal cortex are shown in Fig. 87.6. The adrenal zona glomerulosa is characterized by three features: its expression of angiotensin II receptors, its unique expression of P450c11AS, and its absence of P450c17 expression. This combination of factors permits the zona glomerulosa to produce aldosterone under regulation by the renin/angiotensin system. By contrast, the adrenal zona fasciculata does not express angiotensin II receptors or P450c11AS, but instead expresses the melanocortin type 2 receptor (MC2R, the receptor for ACTH) and P450c11β, which cannot convert 18-hydroxycorticosterone to aldosterone and has minimal capacity to convert corticosterone to 18-hydroxycorticosterone.[187] Both the zona glomerulosa and zona fasciculata express P450c21, but the zona fasciculata also expresses P450c17, which allows cortisol synthesis. The zona fasciculata, however, expresses very little b5[54]; consequently, P450c17 in the zona fasciculata catalyzes 17α-hydroxylation but much less 17,20-lyase activity. Thus, the zona fasciculata produces two glucocorticoids, mainly cortisol and smaller amounts of corticosterone, under the influence of ACTH. Patients with severe mutations in P450c17 cannot synthesize cortisol but instead increase corticosterone production (as do rodent adrenal glands, which normally lack P450c17), explaining why they are not glucocorticoid-deficient, despite the lack of cortisol (see Fig. 87.5). The adrenal zona reticularis also expresses MC2R but very little P450c21, P450c11β, or 3βHSD2, and as a result, the zona reticularis produces minimal amounts of cortisol. By contrast, high b5 expression in the zona reticularis[54] maximizes the 17,20-lyase activity of P450c17,[39] so that DHEA is produced and sulfated by SULT2A1 to DHEAS. As DHEA accumulates, small amounts are converted to androstenedione, and very small amounts of this androstenedione are converted to testosterone, probably by AKR1C3/17βHSD5. Thus, the pattern of steroid products secreted by each adrenal zone is determined by the enzymes produced in that zone and may be logically deduced from an understanding of their specific enzymatic properties.

Gonadal Steroidogenic Pathways

Testicular synthesis of testosterone follows a pathway that is similar to C19-steroid production in the adrenal zona reticularis, with the notable exceptions that Leydig cells express 3βHSD2 and 17βHSD3 but no SULT2A1, and the stimulus for steroidogenesis is transduced by the LH receptor rather than MC2R. Consequently, DHEA produced under LH stimulation is not sulfated but is readily converted to androstenedione and then testosterone, or via androst-5-ene-3β,17β-diol as the intermediate (Fig. 87.6). As in the adrenal gland, the principal pathway to C19 steroids is via Δ^5 steroids to DHEA; the Δ^4 pathway from 17OHP to androstenedione makes a minimal contribution.[39,63] By contrast, ovarian steroidogenesis is more complex, as the enzymatic steps are partitioned between the granulosa and theca cells, which surround the oocyte and form a follicle. In addition, the patterns of steroidogenesis vary during the cycle, directed mainly to estradiol in the follicular phase and to progesterone in the luteal phase (see Fig. 87.6). The key point in ovarian steroidogenesis is that granulosa cells do not express P450c17. Thus, in general, steroidogenesis is initiated in granulosa cells under the influence of LH, which, via cAMP, stimulates the expression of P450scc.[17] Pregnenolone and progesterone from granulosa cells diffuse into adjacent theca cells, where P450c17 and 3βHSD2 can act upon them to produce androstenedione. Some androstenedione is secreted or converted to testosterone (via AKR1C3/17βHSD5), and a portion returns to the granulosa cells, where androstenedione is converted to estrone and then to estradiol by P450aro and 17βHSD1, respectively. Thus, as with the three zones of the adrenal gland, the patterns of gonadal steroidogenesis are dictated by the cell-specific expression of specific steroidogenic enzymes.

The Backdoor Pathway to Dihydrotestosterone

An alternative pathway from 17OHP affords dihydrotestosterone when 17OHP is sequentially 5α- and 3α-reduced to 5α-pregnane-3α,17α-diol-20-one in steroidogenic cells expressing P450c17 (Fig. 87.7*A*).[43] Not only is 5α-pregnane-3α,17α-diol-20-one the most efficient substrate known for the 17,20-lyase activity of human P450c17, but unlike the conversion of 17α-hydroxypregnenolone to DHEA, its conversion to androsterone occurs efficiently without b5.[42] The resulting androsterone may be reduced to 5α-androstane-3α,17β-diol and then 3α-oxidized to dihydrotestosterone, probably by RoDH (17βHSD6). Thus this alternative pathway is a "backdoor pathway" to dihydrotestosterone, which is produced without the intermediacy of DHEA, androstenedione, and testosterone. The backdoor pathway enables production of potent androgens from 17OHP, despite the poor 17,20-lyase activity of human P450c17 for 17OHP, by using 5α-pregnane-3α,17α-diol-20-one as the substrate for the 17,20-lyase reaction.

The human backdoor pathway is relevant to normal physiology and to pathologic states. The only enzymatic activities unique to the backdoor pathway that are not found in "conventional" steroidogenic pathways are the oxidative and reductive 3αHSD activities, but at least one isoenzyme capable of catalyzing each requisite reaction is expressed in appropriate tissues of the human fetus.[44] Mass spectrometric analyses of urinary steroids in patients with POR deficiency confirm that all the steroidal intermediates in the backdoor pathway are produced in patients with POR deficiency.[188] Similar studies have shown that infants, children, and adults with 21-hydroxylase deficiency who overproduce 17OHP, the "gateway steroid" of the backdoor pathway, excrete all the expected urinary metabolites of the backdoor pathway steroids, including high amounts of androsterone (5α-reduced C19 steroid) relative to etiocholanolone (5β-reduced C19 steroid).[45] This androgen production by the backdoor pathway helps to explain why newborn girls with 21- and 11β-hydroxylase deficiencies can be severely virilized, while those with 3βHSD2 deficiency, who cannot generate much intraadrenal 17OHP, are minimally virilized.[46]

Pathways to 11-Oxygenated Androgens

In the testes of teleost fish, nascent testosterone is subject to 11β-hydroxylase and oxidative 11β-hydroxysteroid dehydrogenase activities, yielding 11-ketotestosterone as the major androgen product. The human Leydig cell expresses neither P450c11β nor 11βHSD2, but the human adrenal cortex expresses P450c11β in the zona fasciculata and zona reticularis, where androstenedione can be produced and 11β-hydroxylated. In fact, the concentration of 11β-hydroxyandrostenedione in adrenal vein effluent is higher than androstenedione,[97] and circulating concentrations of 11β-hydroxyandrostenedione exceed those of androstenedione by a factor of 1.5 to 3 in males and females throughout life.[98,189] Circulating 11β-hydroxyandrostenedione is efficiently oxidized via 11βHSD2 in the kidney,[190] yet little 11-ketoandrostenedione accumulates. Instead, 11-ketoandrostenedione is a much better substrate for AKR1C3 than androstenedione by roughly a factor of eight,[191] and thus generates 11-ketotestosteorne via two conversions of the adrenal precursor in peripheral tissues (Fig. 87.7*B*). Furthermore, 11-ketotestosterone is a potent agonist of the human androgen receptor, nearly as active as testosterone.[98]

Figure 87.5 **Major steroidogenic pathways of the human adrenal cortex.** The conversion of cholesterol to pregnenolone is common to all three zones. **A,** In the zona glomerulosa, 3βHSD2 converts pregnenolone to progesterone. P450c17 is absent, but P450c21 produces 11-deoxycorticosterone, which is a substrate for P450c11AS (aldosterone synthase), the enzyme catalyzing 11β-hydroxylation and two 18-oxygenations to complete aldosterone synthesis. **B,** The zona fasciculata expresses P450c17 but little cytochrome b5, so pregnenolone is hydroxylated to 17α-hydroxypregnenolone but not cleaved to DHEA. Instead, 3βHSD2 yields 17α-hydroxyprogesterone, the preferred substrate for P450c21, which produces 11-deoxycortisol. P450c11β, which is unique to the zona fasciculata, completes the synthesis of cortisol. Corticosterone is normally a minor product *(dashed arrows)* derived from a parallel pathway without the action of P450c17. **C,** The zona reticularis has high P450c17 and cytochrome b5 but low 3βHSD2, so pregnenolone is sequentially oxidized to 17α-hydroxypregnenolone and then DHEA. SULT2A1 sulfates DHEA, and DHEAS is exported to the circulation.

Figure 87.6 Major steroidogenic pathways of the gonads. Both the Leydig cell of the testis and the granulosa cell of the ovary convert cholesterol to pregnenolone, and the Leydig and theca cells have the capacity to synthesize androstenedione and testosterone. The major difference in their enzymatic machinery is abundant 17βHSD3 expression in Leydig cells (**A**), which efficiently completes testosterone synthesis in the testis, whereas androstenedione is the major C19 product of the theca cell (**B**). The granulosa cells of the ovary contain abundant aromatase and 17βHSD1, which complete the biosynthesis of estradiol. Minor pathways are shown with *dashed arrows.*

Figure 87.7 Additional important pathways in human androgen biosynthesis. **A,** The two pathways to DHT using the different 17,20-lyase activities of human P450c17. In the conventional or Δ5-pathway *(solid arrows),* the 17,20-lyase activity of P450c17 requires cytochrome b_5 to efficiently convert 17α-hydroxyprogesterone to DHEA, and testosterone is reduced in target tissues by 5α-reductase 2 (5αR2) to DHT. In the "backdoor" or 5α,3α-pathway *(broken arrows)*, 5α-reduction by 5αR1 and 3α-reduction of C21 steroids occurs in the steroidogenic tissue prior to the 17,20-lyase reaction. In the best characterized pathway, 5α-pregnane-3α,17α-diol-20-one is cleaved to androsterone without requiring cytochrome b5 and reduced to 5α-androstane-3α,17β-diol. The 5α-androstane-3α,17β-diol is exported from the testis and metabolized to DHT by oxidative 3αHSDs (Ox. 3αHSD, probably 17βHSD6). Note that testosterone is not an intermediate in the backdoor pathway to DHT, that different isoforms of 5α-reductase appear to be involved in the two pathways, and that both reductive and oxidative 3αHSDs are required for the backdoor pathway. **B,** The 11-oxygenated androgen pathway. The major substrate is androstenedione, which is 11β-hydroxylated via P450c11β to 11β-hydroxyandrostenedione in the adrenal cortex. Primarily in peripheral tissues, the enzyme 11βHSD2 oxidizes this adrenal product to 11-ketoandrostenedione, which is an excellent substrate for AKR1C3. The 17β-reduction via AKR1C3 yields 11-ketotestosterone, a potent androgen, which can be further 5α-reduced to 5α-dihydro-11-ketotestosterone. Additional minor pathways are also shown.

Continued

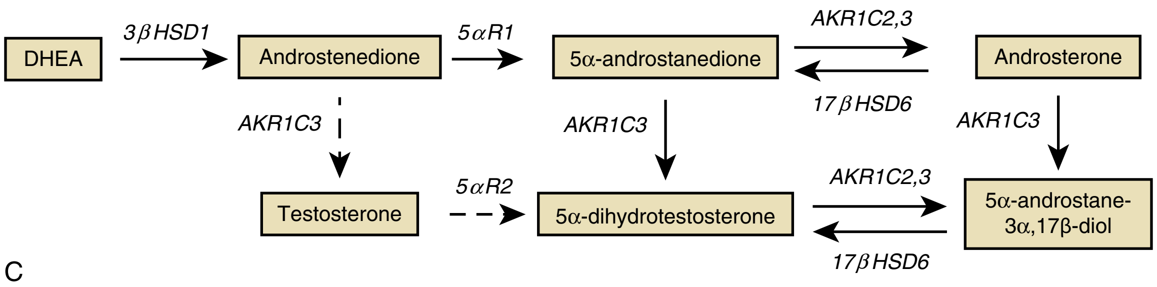

Figure 87.7, cont'd C, DHEA metabolism in castration-resistant prostate cancer cells. DHEA is converted to androstenedione via 3βHSD1, which is then 5α-reduced by 5α-reductase type 1 (5αR1) to 5α-androstanedione. AKR1C3 completes the pathway to dihydrotestosterone, and AKR1C enzymes plus 17βHSD6 reversibly convert these 5α-reduced steroids to other side products.

In children with premature adrenarche[98] and premature pubarche,[192] circulating 11-ketotestosterone is elevated compared to age-matched controls and 2- to 3-fold higher than testosterone, regardless if DHEAS is elevated. Thus, while DHEAS might be the traditional biomarker of adrenarche, it is 11-ketotestosterone that is the dominant circulating and biologically active androgen that yields the physical manifestations of adrenarche. Circulating concentrations of both 11β-hydroxyandrostenedione and 11-ketotestosterone exceed those of androstenedione and testosterone, respectively, in conditions of adrenal-derived androgen excess with preserved 11β-hydroxylase activity, most prominently undertreated 21-hydroxylase deficiency.[193,194] Note that 11-oxygenated androgen production is not elevated in 11β-hydroxylase deficiency or 3β-hydroxysteroid dehydrogenase deficiency, because 11β-hydroxylase activity is low or androstenedione is generated outside the adrenal cortex, respectively.

In addition, circulating concentrations of 11β-hydroxyandrostenedione exceed those of androstenedione by at least a factor of two in most men and women,[189] whereas 11-ketotestosterone is the dominant circulating androgen in prepubertal children[98] and is slightly higher than testosterone most women.[189] Furthermore, while circulating concentrations of DHEAS, androstenedione, and testosterone all decline with age in men and women after early adulthood, those of 11β-hydroxyandrostenedione and 11-ketotestosterone are preserved without much change in healthy adults until the ninth decade of life.[189] These observations are paralleled during aging by changes in the different zones of the adrenal cortex, with an expansion of the zona fasciculata, despite reduction in zona reticularis and the zona glomerulosa (in men), so allowing preservation of 11β-hydroxylase activity that may then account for the preservation of 11β-hydroxyandrostenedione and 11-ketotestosterone levels.[195] Additional studies demonstrate that the 11-oxygenated androgens are substrates for the 5α-reductases (Fig. 87.7*B*), which amplifies the activity of 11-ketotestosterone.[196] Thus, the 11-oxyandrogens are not curiosities or minor adrenal side-products, but rather important contributors to human physiology in children and women and to disease states, including 21-hydroxylase deficiency, polycystic ovary syndrome, prostate cancer, and possibly to other conditions related to advanced age.[99]

Androgen Synthesis in Prostate Cancer

The classical paradigms of steroidogenesis reflect the enzymes and pathways present in endocrine glands, which generate enough steroids to maintain circulating concentrations high enough to activate their cognate receptors in various tissues. Much less flux is required for a cell to generate biologically significant amounts of hormones—either from cholesterol or from circulating intermediates—to activate the receptors in the same tissues, in an autocrine or intracrine manner. Under these circumstances, minor reactions, different enzymes, and modified pathways may dominate. CRPC is an example of this scenario, in which minute amounts of testosterone or dihydrotestosterone are sufficient to fuel disease progression. Most of the cognate mRNAs for the enzymes and proteins necessary to synthesize dihydrotestosterone from cholesterol are upregulated in CRPC metastases relative to primary tumors, and androgen concentrations in the metastases are preserved.[197] Given that the abundance of most of the enzymes in the early steps is still quite low, however, it is not clear whether the majority of androgens in CRPC cells derive entirely from de novo synthesis or from metabolism of circulating intermediates.[68] Abundant circulating DHEA and DHEAS could serve as the precursor, requiring only two to four steps to testosterone and dihydrotestosterone. The conversion of DHEA to dihydrotestosterone has been well documented in CRPC samples and in prostate cancer cell lines derived from such tumors.[198] In these cells, the dominant pathway is oxidation of DHEA to androstenedione via 3βHSD1 (not 3βHSD2), then 5α-reduction of androstenedione to 5α-androstanedione via 5α-reductase type 1 (not type 2), followed by reduction of 5α-androstanedione to dihydrotestosterone via one or more 17βHSDs (Fig. 87.8*C*).[163] In addition, dihydrotestosterone production via the "backdoor" pathway appears to occur,[68] and oxidation of 5α-androstane-3α,17β-diol to dihydrotestosterone has been demonstrated.[199] To complicate matters, AKR1C3, which may catalyze the critical (activating) 17β-reduction of 17-ketosteroids to testosterone and dihydrotestosterone, also catalyzes the (inactivating) 3α-reduction of dihydrotestosterone, as does AKR1C2.[199] Consequently, it is difficult to predict how changes in enzyme expression translate to shifts in the delicate balance between intracellular androgen synthesis and degradation. The evolving biology of androgen synthesis in CRPC continues to revise our traditional concept of steroidogenic pathways and to identify additional potential therapeutic targets.

KEY POINTS

- In the adrenal, zone-specific expression of differing steroidogenic enzymes and receptors to adrenocorticotropic hormone and angiotensin II determine the specific repertoire and regulation of the steroids synthesized.
- The human backdoor pathway is relevant to normal physiology and to pathologic states.
- 11-Oxygenated androgens are important in disease states, including 21-hydroxylase deficiency, polycystic ovary syndrome, prostate cancer, and possibly to other conditions related to advanced age.

Summary and Future Directions, 1481

The steroid hormone aldosterone first appeared in vertebrate evolution with the emergence of terrestrial life and the consequent need to conserve sodium and water.[1] The primary and best-characterized actions of aldosterone are those that stimulate sodium retention in transporting epithelia, particularly the distal nephron, distal colon, and salivary glands.[1] In these epithelia, the conservation of sodium is associated with an increased secretion of both potassium and hydrogen ions. Aldosterone also has actions in the cardiovascular system, in inflammatory cells, in adipose tissue, and in the central nervous system (CNS).

The existence of an adrenocorticoid natriuretic factor, distinct from the other adrenal steroid hormones, had been suspected for several years before its isolation by Simpson and colleagues in 1953.[2] Using the toad urinary bladder as a model system, Crabbé[3] was the first to show that aldosterone increases sodium transport *in vitro*. Subsequent studies demonstrated the presence of binding sites for aldosterone in the toad bladder and in other target tissues, particularly the principal cells of the cortical collecting duct of the kidney.[4]

FEEDBACK CONTROL OF ALDOSTERONE SECRETION

Both serum sodium concentration and total body sodium are maintained within a narrow range by a complex set of endocrine feedback loops (Fig. 88.1). The most important of these involves the renin-angiotensin-aldosterone system (RAAS), which responds to volume status. The feedback loops involved with potassium homeostasis operate in parallel and overlap those for sodium.

The renin-secreting juxtaglomerular cells of the kidney sense volume status. When the sodium status (and hence, intravascular volume) is low, renin will be secreted. Renin is an aspartyl protease that is synthesized as inactive prorenin and subsequently activated by the action of a protease. Renin release from the juxtaglomerular cells is influenced by several factors (Table 88.1). Stimulatory regulators include renal perfusion pressure, sympathetic nervous system, and prostaglandins, while inhibitory factors include dopamine, atrial natriuretic peptide (ANP) and angiotensin II (AngII). Renin cleaves angiotensinogen to release the decapeptide angiotensin I, which in turn is subject to further proteolysis by angiotensin-converting enzyme 1, primarily in the pulmonary vascular bed, to yield the octapeptide AngII. Ang II acts via its specific G protein–coupled receptor, the type 1 AngII receptor (AT1R), in the vasculature as a potent vasoconstrictor (thereby defending plasma volume and blood pressure) and on the adrenal glomerulosa cells to stimulate aldosterone synthesis.[5] The latter response promotes sodium retention, with a consequent increase in intravascular volume. Aldosterone biosynthesis in the zona glomerulosa of the adrenal cortex is regulated by transcription of the aldosterone synthase gene (*CYP11B2*), which encodes the last and rate-limiting step in aldosterone biosynthesis (see Chapter 87). Although AngII is important in the regulation of aldosterone synthase activity, a response to low-salt or high-potassium diets is also seen in mice in which the angiotensinogen gene has been deleted.[6] In these mice, the regulation of aldosterone is primarily directed by serum potassium levels. Both AT1R and potassium interact with potassium channels in the glomerulosa cell membrane. These channels maintain the hyperpolarization of the cell membrane; depolarization of the membrane through changes in ion flux through these channels results in an increased calcium flux, with consequent stimulation of aldosterone secretion. Experimental and clinical studies have identified channels involved in this coupling, including TWIK-related acid sensitive channels, GIRK4 (G protein–activated inward rectifier potassium channel 4), an inward-rectifying potassium channel encoded by the *KCNJ5* gene, the α1 subunit of Na^+/K^+-ATPase encoded by the ATP1A1 gene, PMCA3 (plasma membrane Ca^{2+}-ATPase type 3) encoded by the ATP2B3 gene, Cav1.3 (a voltage-dependent calcium channel) encoded by the *CACNAID* gene, and

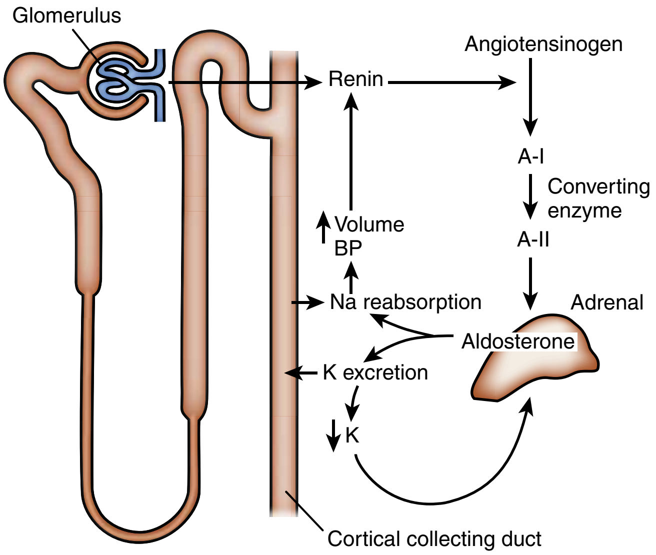

Fig. 88.1 Interacting feedback loops controlling aldosterone secretion. Volume is regulated through the renin-angiotensin system, and potassium is regulated through direct feedback. *A-I*, Angiotensin I; *A-II*, angiotensin II; *BP*, blood pressure; *Na*, sodium; *K*, potassium.

TABLE 88.1 Factors Regulating Renin Release

Stimulatory	Inhibitory
Decreased perfusion pressure	Increased chloride delivery at the macula densa
PGI_2	Angiotensin II
ACTH	Atrial natriuretic factor
	Vasopressin
β-adrenergic stimulation	α-adrenergic stimulation
	Dopamine

ACTH, Adrenocorticotropic hormone; *PGI_2*, prostacyclin.

ClC-2 (chloride channel protein 2) encoded by the CLCN2 gene.[7] Somatic mutations in the *KCNJ5*, *ATP1A1*, *ATP2B3*, or *CACNAID* genes are found in approximately 88% of aldosterone-producing adenomas,[7] as discussed in Chapter 96.

The secretion of aldosterone stimulated by potassium forms one arm of a negative feedback loop for potassium and aldosterone that this independent of AngII levels. Small increases in extracellular potassium levels stimulate calcium influx via depolarization of the glomerulosa cell plasma membrane. Plasma potassium levels also alter the sensitivity of the adrenal to AngII.

Aldosterone also affects acid–base balance by increasing the exchange of hydrogen ions for sodium. Therefore, the net effect of an increase in aldosterone, as may result from an aldosterone-producing tumor or exogenous mineralocorticoid administration (e.g., 9α-fludrocortisone), is sodium resorption, with consequent volume expansion, hypertension, and suppression of plasma renin activity, hypokalemia, and metabolic alkalosis (Chapter 96).

The third principal regulator of aldosterone synthesis is adrenocorticotrophic hormone (ACTH), whose primary role is the regulation of cortisol synthesis in the adrenal fasciculata in the feedback loop between the pituitary corticotropes and the adrenal cortex, the hypothalamo-pituitary-adrenal axis (Chapter 85). ACTH acutely increases aldosterone synthesis, but chronic ACTH exposure results in a decrease in the levels of CYP11B2, and hence aldosterone synthesis[8]; however, regulation of aldosterone synthesis is normal in patients with hypopituitarism.[9]

TABLE 88.2 Factors Regulating Aldosterone Secretion

Factor	Stimulatory	Inhibitory
Peptides	Angiotensin II	Atrial natriuretic peptide
	Angiotensin III	Somatostatin
	ACTH	
	Vasopressin	
	Endothelin	
Ions	Plasma potassium	
Other	Serotonin	Dopamine
	Substance P	Ouabain

ACTH, Adrenocorticotropic hormone.

Other substances that have been shown to regulate aldosterone secretion are shown in Table 88.2. For example, intraadrenal regulation of aldosterone secretion has been proposed for substance P–positive nerve fibers. In the adrenal zona glomerulosa, a stimulatory tone for aldosterone secretion maintained by substance P acting via the neurokinin type 1 receptor on zona glomerulosa cells.[10] Serotonin is exclusively synthesized and produced by adrenal subcapsular mast cells; it stimulates aldosterone secretion through a paracrine mechanism involving the serotonin type 4 receptor.[11] The physiological and pathophysiological significance of these local regulators of aldosterone secretion is the subject of ongoing investigation. Aldosterone secretion is also subject to negative regulation. ANP is a potent inhibitor of aldosterone secretion, consistent with its role in promoting natriuresis. Dopamine is also a well-characterized inhibitor of aldosterone secretion. Other inhibitors have been described, but their physiologic relevance is even less clear.

KEY POINTS

- Aldosterone synthesis/secretion is primarily regulated by angiotensin II and potassium in two parallel feedback loops.

SODIUM HOMEOSTASIS

Under normal physiological conditions, over 99% of the sodium filtered through the glomerulus is reabsorbed along the nephron: approximately 70% by the proximal tubules, 20% to 30% by the thick ascending limb of Henle, 5% to7% by the distal convoluted tubules (DCTs), and finally by the aldosterone-sensitive connecting tubules (and cortical collecting ducts.[12] As the final arbiter of sodium excretion, these aldosterone-sensitive segments are thus pivotal. The RAAS contributes to an integrated homeostatic response to fluctuations in dietary sodium intake.[13] Sodium deficiency increases adrenal sensitivity to AngII through time; the converse is true of the vasopressor response. Aldosterone-induced sodium retention restores intravascular volume status by maintaining the balance between volume and vascular capacity.[12,13]

The response of the individual to aldosterone-mediated sodium retention is self-limiting, in that, after 3 to 4 days, the expansion of extracellular volume plateaus and sodium secretion returns to control levels. This process is termed *escape*.[14] It should be noted that the kaliuretic effect persists despite the escape of sodium retention. Intrarenal regulators, particularly prostaglandins, are probably the critical mediators of the escape, although other factors (e.g., ANP) may play a role.[15]

Other epithelia, particularly the distal colon, contribute to aldosterone-mediated sodium homeostasis through mechanisms that parallel those in the distal nephron. In addition, nuclei within the brain contribute to the regulation of salt appetite.[16]

A local RAAS has been reported to operate in a number of tissues, although the relative physiologic versus pathophysiological importance of these local systems remains unresolved.[5]

POTASSIUM HOMEOSTASIS

Aldosterone is primarily involved in the chronic regulation of plasma potassium levels.[17] Acute regulation involves nonrenal mechanisms such as those mediated by insulin and β-adrenergic agonists. Aldosterone regulates potassium homeostasis through direct effects on transporting epithelia. Potassium flux occurs in the principal cells of the collecting duct in response to aldosterone-mediated sodium reabsorption, with the resulting electrochemical gradient favoring potassium excretion at the basolateral membrane.[17a] Aldosterone also regulates potassium transport in the distal nephron independent of the sodium flux. The collecting duct contains intercalated cells, which have well-recognized roles in potassium and acid–base homeostasis.[18]

SPECIFICITY-CONFERRING ENZYMES

Prereceptor metabolism (activation or inactivation) is seen for several steroid hormones, including the corticosteroids. The physiological glucocorticoid, cortisol (corticosterone in rodents), is synthesized in the adrenal fasciculata, and also in the periphery, particularly the liver, by the conversion of cortisone (11-dehydrocorticosterone in rodents) to the active glucocorticoid by the enzyme 11β-hydroxysteroid dehydrogenase type 1 (11β-HSD1), a member of the short-chain dehydrogenase/reductase family of microsomal enzymes. The reverse reaction, mediated by the 11β-HSD type 2 isoform (11β-HSD2), mediates the conversion of cortisol to the inactive metabolite, cortisone, thereby enabling the mineralocorticoid actions of aldosterone.[19]

11β-Hydroxysteroid Dehydrogenase Type 2

Although the affinity of the mineralocorticoid receptor *in vitro*[20] is equivalent for aldosterone, corticosterone, and cortisol, *in vivo* cortisol is excluded from such receptors in the kidney, parotid, and colon (but not in the hippocampus).[19] This reflects the activity of 11β-HSD2, which is responsible for the conversion of cortisol to its inactive metabolite, cortisone. In the kidney, this is reflected in the reduced cortisol:cortisone ratio in human renal venous blood. Unlike 11β-HSD1, 11β-HSD2 colocalizes with MR in renal distal tubular elements, colon, sweat, and salivary glands; it is also expressed at high abundance in the placenta and in select nuclei in the rat brain.[16] It has a low Km (i.e., high affinity) for both corticosterone (~5 nM) and cortisol (~50 nM), unlike the micromolar Km of 11β-HSD1; *in vivo*, it appears operationally unidirectional, acting uniquely as a dehydrogenase, whereas 11β-HSD1 acts predominantly as a reductase.[19] Deletion of the gene encoding 11β-HSD2 in mice yields a phenotype[19] consistent with the clinical syndrome of apparent mineralocorticoid excess.[21,22]

Liquorice ingestion has long been known to cause sodium retention, hypokalemia, and hypertension; the mechanism of its action was elucidated by elegant studies[23,24] in human volunteers, in whom ingestion of 250 g of liquorice per day for 10 days produced a clinical picture equivalent to a mild form of apparent mineralocorticoid excess. When rats were administered glycyrrhetinic acid (the active principal of liquorice) or carbenoxolone (glycyrrhetinic acid hemisuccinate)[25] to block 11β-HSD, the normal aldosterone selectivity of epithelial MR was abolished. These studies demonstrated the crucial specificity-conferring role in mineralocorticoid target tissues for 11β-HSD2. Aldosterone is not a substrate for 11β-HSD2, because its 11β-OH group is stabilized as an 11,18-hemiketal by cyclization with the highly reactive aldehyde group unique to aldosterone at C18.

KEY POINTS

- Aldosterone selectivity of the MR in epithelial tissues is conferred by 11β-hydroxysteroid dehydrogenase type II.

MINERALOCORTICOID RECEPTORS

The classic actions of aldosterone in the distal nephron and distal colon involve epithelial cells that mediate sodium flux. As with other steroid hormones, the principal mode of action, at least in sodium transport, involves an intracellular receptor that, when activated by ligand binding, regulates gene transcription, a so-called genomic mechanism of action.

High-affinity cytosol and nuclear binding of ^{3}H-aldosterone was first described in classic mineralocorticoid target tissues such as kidney and parotid gland.[4] Spironolactone was shown to block aldosterone binding and action on urinary electrolytes in parallel,[26] providing evidence that these sites are physiologic MRs. In contrast to glucocorticoid receptors (GRs), which are expressed ubiquitously, MRs have a tissue-specific pattern of expression, with the highest levels observed in the distal nephron,[20,27] distal colon,[28] and hippocampus.[20] Lower levels of expression are observed elsewhere in the gastrointestinal tract, in cardiovascular tissues, in regions of the brain, and in a range of other tissues that are both epithelial and nonepithelial.[20,27,28] In these nonepithelial tissues, a physiologic effect of MR activation on sodium homeostasis is unlikely (e.g., hippocampus).

The MR is unique among the steroid hormone receptors in that it is a receptor for two physiologic agonists, aldosterone and cortisol; indeed, the MR has a higher affinity for cortisol than does the GR.[20] Progesterone is a physiological competitive antagonist of the human MR.[29]

KEY POINTS

- Aldosterone activates the mineralocorticoid receptor (MR), a member of the nuclear receptor superfamily.

Evolution

The MR is found only in vertebrates; it diverged with the GR as a gene duplication from the ancestral corticoid receptor gene over 450 million years ago.[30] This ancestral corticoid receptor first appeared in cartilaginous fish and is found in lamprey and hagfish (jawless fish). Aldosterone first appeared as an active steroid in amphibians. It has been postulated that the MR originated in fish to regulate ion balance under the control of glucocorticoids, and that amphibians evolved mineralocorticoids to appropriate the MR for this function. In most tetrapods (including human, rodent, alligator, and *Xenopus*) progesterone is an antagonist of MR, as is its pharmacologic derivative spironolactone.[29] Although the MR is present in teleost fish that lack aldosterone synthesis, the teleost MR responds to aldosterone, as well as to cortisol and 11-deoxycorticosterone, consistent with the MR being highly conserved throughout vertebrate evolution.[29,31] Characterization of various fish MRs found that, in contrast to terrestrial vertebrate, teleost MRs were activated by both progesterone and spironolactone.[29] These findings suggest that progesterone may be a physiological agonist for the MR in teleosts. Curiously, this evolutionary switch of the MR response to progesterone from agonist to antagonist reflects a single amino acid change in the MR[31] that occurred at the time of the appearance of aldosterone synthesis in terrestrial vertebrates. The physiological significance of the MR as a progesterone receptor (PR), or perhaps as a receptor for a progesterone metabolite, has not been fully characterized.[32]

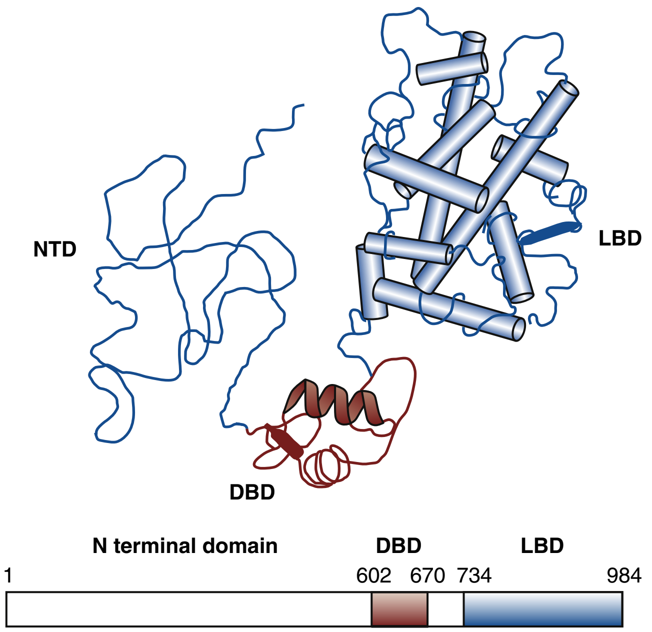

Fig. 88.2 Domain structure of the mineralocorticoid receptor showing the three principal functional domains, including the N-terminal domain (*NTD*), the DNA-binding domain (*DBD*), and the ligand-binding domain (*LBD*). A predicted tertiary structure is shown above the linear representation.

KEY POINTS

- The MR is unique, being the receptor for two physiologic ligands: aldosterone and cortisol.

Structure

The human MR is a protein of 984 amino acids,[20] which, with the GR, PR, and androgen receptor (AR), forms a distinct subfamily within the steroid/thyroid/retinoid/orphan receptor superfamily. A central cysteine-rich DNA-binding domain (DBD) defines this receptor superfamily. At the C-terminus is the ligand-binding domain (LBD), which has a highly conserved tertiary structure. The N-terminal domain has little or no homology between receptors. Within the MR/GR/PR/AR subfamily, MR and GR are closely related, with 94% amino-acid identity in the central cysteine-rich DBD and 57% identity in the C-terminal LBD (Fig. 88.2). The genes encoding MR and GR are, however, located on different chromosomes (MR on 4q31.2; GR on 5q31).[33,34]

The cysteine residues of the DBD complex around two zinc atoms to form two α-helices, one of which lies in the major groove and binds with a common consensus sequence in the DNA, the hormone response element (HRE).[35] This element is an inverted palindrome that appears to be similar, if not identical, to the well-characterized GR response element (GRE). Several groups have sought to characterize the genome-wide distribution of the HRE for the MR, the MR cistrome, using chromatin immunoprecipitation with massive parallel sequencing, with differing outcomes. A study using a transformed human renal cell line identified 974 MR binding sites, the majority of which, somewhat surprisingly, did not include canonical GRE but did contain recognition motifs for other transcription factors,[36] whereas in a murine epithelial cell line 1113 binding sites were identified, with many containing the consensus GRE sequence.[37]A total of 918 unique MR binding sites were identified in rat hippocampus that included the well-characterized canonical GRE sequence; the MR-specific binding sites included a motif known to bind the NeuroD family of transcription factors.[38]

The LBD consists of 11 α-helices (designated helix 1 to 12 based on the estrogen receptor structure: helix 2 is unstructured in the MR) that form a three-layered antiparallel structure with the ligand-binding pocket buried in the lower third of the struture.[39-41] The N-terminal domain, by contrast, is relatively unstructured, allowing a diversity of interactions.[42] The N-terminal domains are not conserved between steroid receptors, although in several (including the MR) a functional interaction has been described between the N- and C-termini.[43]

The unliganded receptor is predominantly cytoplasmic, being complexed with the heat shock proteins 70 and 90 and their cochaperones.[44] This configuration maintains the receptor in a transcriptionally inactive high-affinity binding state. The interaction of the LBD with this complex is an important determinant of ligand-binding affinity and specificity. The MR antagonists spironolactone and eplerenone appear to be accommodated into the ligand-binding pocket without distortion, suggesting that the mechanism of their antagonism differs from that of the estrogen receptor antagonists such as tamoxifen and raloxifene.[40] In nonepithelial tissues, the response of MR to cortisol/corticosterone and aldosterone is often not equivalent, leading to speculation about the relationship of epithelial to nonepithelial MR. Most evidence to date would suggest that, although transcription of the gene encoding MR is activated through multiple, tissue-specific promoters,[45] the coding region is unaltered between tissues, with the possible exception of some minor isoforms.[46] The explanation for such differences in MR target gene activation by the various ligands may lie in the nature of the conformation that the MR adopts after ligand binding.[47] Such conformational differences may alter some, but not all, transactivation functions, such that tissue-specific receptor coactivators or corepressors may mediate different responses in different tissues. In contrast to the other steroid receptors, such interactions are only now being characterized for the MR. Several MR coactivator molecules have now been described, including some with ligand specificity.[48] The interaction of these coregulators with the LBD, as with other nuclear receptors, involves a surface pocket that interacts with an LxxLL motif (where L is leucine and x is any amino acid) in the coactivator molecule.[41]

Other factors also appear to modulate MR signaling, including Rac1 (Ras-related C3 botulinum toxin substrate1), a small RhoGTPase, which may play a role in regulating nuclear translocation of transcription factors and has been reported to activate MR through both ligand-dependent and ligand-independent mechanisms.[49]

In addition to its effects on ion flux in classic mineralocorticoid target tissues, aldosterone has been shown act via the MR to mediate a range of responses, unrelated to sodium homeostasis, in other tissues. Aldosterone elevates blood pressure in the rat when infused into the cerebral ventricles[50]; this effect is clearly via MR unprotected by11β-HSD2, because it is blocked by simultaneous infusion of low doses of corticosterone. Thus, corticosterone in the anteroventral third ventricle region acts as an aldosterone antagonist on MR, in contrast with the kidney and other epithelia, where its action is to mimic aldosterone. An additional difference between epithelial and nonepithelial tissues is that, in the former, activation of GR has been shown to mimic that of MR, whereas in nonepithelial tissues this is clearly not the case.

Mice homozygous for inactivating mutations in the gene encoding MR[51] (MR knockout; MRKO) showed classic features of aldosterone deficiency—salt wasting, hyperkalemia, and dehydration—but had marked hyperaldosteronism; these features are also seen in the syndrome of pseudohypoaldosteronism (PHA) type 1. In patients with PHA1, neonatal salt wasting results in hypovolemia with high renin and aldosterone levels, hyperkalemia, and resistance to exogenous mineralocorticoids (9α-fludrocortisone). MRKO mice are born at the expected frequency from heterozygote mating; untreated, they begin to deteriorate from day 5, and die between day 8 and 11; salt supplementation allows survival and growth. Mutations of the gene encoding MR have also been reported in the autosomal dominant form of PHA,[52] which thus appears to be equivalent to mice heterozygous for the MR gene knockout.

Genomic Versus Nongenomic Aldosterone Actions

As with other steroid hormone receptors, the principal mode of action involves the ligand-activated MR binding to specific responses elements in the genes targeted for transcriptional control. Mice homozygous for an inactivating mutation in the DBD of the MR phenocopy MRKO mice, demonstrating the essential role of DNA binding for MR signaling, at least in sodium-transporting epithelial tissues.[52]

For several other steroid hormone receptors there is an alternate mode of action, again involving regulation of gene expression, but where the steroid receptor interacts with other transcription factors, including other nuclear receptors, to modulate their signaling, a mechanism described as transrepression or tethering.[53] The relevance of this mode of signaling to the MR remains to be clearly defined.

There has also been considerable interest with respect to steroid hormone action as to whether all responses are mediated through the classic nuclear receptor with direct regulation of gene expression, or whether other pathways involving novel cell membrane receptors exist. The evidence for novel receptors is focused on the seven-transmembrane G protein–coupled receptor GRP30, also known as the G protein estrogen receptor.[54] There is clear evidence both *in vitro* and *in vivo* for rapid, nongenomic signaling. This can involve activation of intracellular kinases such as Src kinase associated with the epidermal growth factor receptor, with consequent downstream signaling through the MAP kinase pathway; the signaling appears to require only the LBD of the MR.[55] Rapid effects of aldosterone have also been reported to be associated both with protein kinase signaling[56] in isolated cell patches from cardiomyocytes[57] and in vascular cells[58] and with glutamate release from the pyramidal neurons of the hippocampus.[59] In each case the receptor involved is the classic MR. The relative contribution of this signaling to the mineralocorticoid response has not yet been evaluated, although it is speculated that these rapid responses may prime the transcriptional response or alter the dynamic range of the response.

CELLULAR MECHANISMS OF ALDOSTERONE ACTION

As the term *mineralocorticoid* implies, the classic effects of aldosterone reflect its role in the regulation of electrolyte flux across transporting epithelia. The molecular basis of the regulation of sodium transport in the distal nephrons is relatively well-characterized. The molecular mechanisms that mediate the more recently defined roles of aldosterone in the central regulation of blood pressure,[50] in salt appetite,[16] and in the pathogenesis of cardiac fibrosis[60] are less well understood. Emerging evidence points strongly to a proinflammatory, profibrotic effect of MR activation in cardiovascular tissues consistent with the clinical observation that hypertension secondary to hyperaldosteronism is associated with worse cardiovascular outcomes than idiopathic hypertension.[60]

Sodium Transport

Aldosterone increases transepithelial sodium flux in a number of target tissues, of which the amphibian bladder, the mammalian distal nephron, and the mammalian distal colon are the best characterized.[1] The temporal pattern of response comprises a lag period (latent phase) of 30 to 60 minutes, followed by an early phase in which preexisting pumps and channels are activated, followed by a so-called late phase.[61] This late phase starts 3 to 6 hours after steroid exposure and is characterized by an increase in the number of pumps and channels; with longer exposure, morphologic as well as functional changes are observed.[62] The latent phase is consistent with the concept that the effects of aldosterone are primarily genomic, with the genes regulated by the MR either mediating sodium transport *per se* or modulating components of the transport pathway. In the classic model of aldosterone-induced transport, sodium entry at the apical membrane is through an amiloride-sensitive electrogenic sodium channel, with efflux at the basolateral membrane via the sodium pump, with adenosine triphosphate (ATP) generation needed to drive the process (Fig. 88.3).[1]

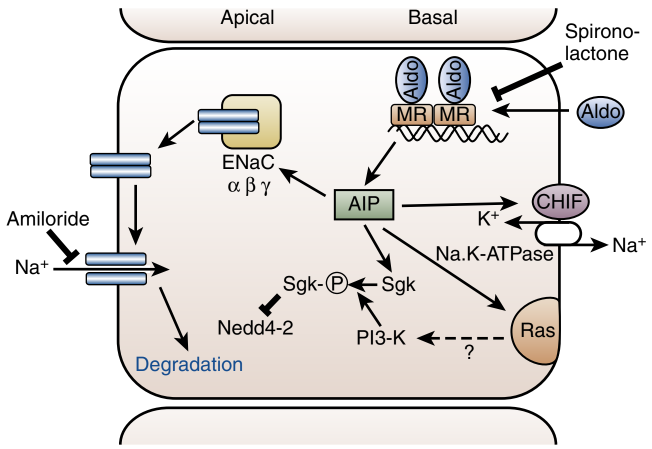

Fig. 88.3 Aldosterone (*Aldo*) acts on epithelial cells of the distal nephron and the distal colon via the mineralocorticoid receptor to induce aldosterone-induced proteins (*AIPs*). *ENaC*, Epithelial sodium channels; *sgk*, serum and glucocorticoid-induced kinase; *CHIF*, channel-inducing factor; *PI3-K*, phosphoinositide 3-kinase; *Na+*, sodium; *K+*, potassium.

KEY POINTS

- Aldosterone-induced epithelial sodium transport involves the epithelial sodium channel at the apical membrane and Na+/K+-ATPase at the basolateral membrane.

Epithelial Sodium Channels

Although a variety of amiloride-sensitive sodium channels have been identified in epithelia, only one has been clearly shown to be directly involved in aldosterone-dependent sodium transport. The epithelial sodium channel (ENaC) genes encode three homologous subunits (α, β, and γ).[63] Each subunit consists of two transmembrane domains with intracellular N- and C-termini. When the α subunit is expressed in *Xenopus* oocytes, a weak amiloride-sensitive sodium flux can be demonstrated; expression of the other subunits alone is without activity, and coexpression of all three subunits is required for maximal amiloride-sensitive sodium transport.[63] The subunits exhibit a heterotrimeric complex of the three subunits, α, β, and γ, arranged in a counter-clockwise manner.[64]

The genes for the ENaC subunits are members of the degenerin (DEG)/ENaC superfamily of sodium channels; the DEGs mediate mechanosensory transduction in *Caenorhabditis elegans*.[63] The ENaCs are unique among the DEG/ENaC channels in being activated by proteolysis of the extracellular domain to release inhibitory peptides. These serine proteases act synergistically with aldosterone to increase channel opening probability.[63]

Insights into the structural determinants of function of the ENaC subunits has come from a combination of both naturally occurring and engineered mutations. Deletion of the *αENaC* gene in transgenic mice results in early neonatal death caused by defective clearance of lung liquid[66]; partial genetic restoration of *αENaC* expression in these mice results in a phenotype similar to that seen in PHA. Mice with the *βENaC* or *γENaC* gene deleted show a less severe pulmonary phenotype but die between 24 and 36 hours with salt wasting and profound hyperkalaemia, again reminiscent of PHA[67,68]; low levels of *βENaC* subunit gene expression in mice in which the *βENaC* gene has been disrupted also result in a milder phenotype analogous to PHA.[69] Autosomal recessive PHA is indeed associated with inactivating mutations of genes encoding all three of the ENaC subunits.[70]

The molecular characterization of Liddle syndrome[71] also provided important insights into the function of the C-terminal intracellular domain and emphasized the central role of the channel in amiloride-sensitive sodium transport. Liddle syndrome, or pseudoaldosteronism, has the reciprocal pathophysiology to PHA,[71] with apparent aldosterone excess (i.e., hypertension, hypokalemia, and suppressed plasma renin activity) but low aldosterone levels, and no response to spironolactone but a response to amiloride. A number of studies have identified mutations in either the *β*- or *γENaC* genes. The mutations are either nonsense or missense mutations localized to the C-terminus; the latter are particularly informative, because they identify a key motif, proline-proline-proline-X-tyrosine (PY), which is conserved across the subunits and is disrupted in all cases of Liddle syndrome.[72] ENaC is a relatively short-lived protein that is ubiquitinated on residues in the N-terminus of the α and γ but not the β subunits; the PY motif interacts with Nedd4-2, a ubiquitin protein-ligase whose role is to target the channels for proteosomal degradation.[73]

These studies demonstrated the central role of the ENaC in mediating aldosterone-induced epithelial sodium transport. ENaC subunit gene expression is regulated by aldosterone.[1] Both β- and γENaC subunit mRNA levels are increased in the colon by sodium depletion and by dexamethasone or aldosterone treatment; in the kidney, however, levels remained unaltered, although when separate regions of the kidney were distinguished, an increase in αENaC mRNA levels was seen in the inner medulla. Cultured medullary collecting duct cells show increased α- but not β- or γENaC mRNA levels after 3 hours of aldosterone exposure; in cultured cortical collecting duct cells, a γENaC subunit response to aldosterone required 24 hours of treatment.[74] Although it is clear from the aforementioned studies that aldosterone can induce ENaC synthesis (at least in the late phase), a transcriptional effect of the MR in the early phase (i.e., a primary response) has not clearly been demonstrated.

Aldosterone treatment *in vivo* rapidly increases the levels of the serine threonine kinase serum and glucocorticoid-regulated kinase (Sgk) in the kidney and colon, with a time course consistent with an effect of aldosterone on transcription.[75,76] Sgk directly interacts with Nedd4-2 to block its binding with ENaC and, as a consequence, slows ENaC degradation.[77,78] Regulation of αENaC subunit gene expression involves Sgk-1 through relief of Dotla-Af9-mediated transcriptional repression.[79] Nedd4-2 is also regulated by Usp2-45, a deubiquitinylation enzyme that is itself regulated by aldosterone.[80] Sgk requires phosphorylation by the phosphatidylinosital 3-kinase (PI3 kinase) pathway for full activity. This may be a point at which the signaling of nuclear receptors and membrane-associated receptors such as the insulin receptor are integrated.[81] PI3 kinase may be activated by small monomeric G proteins, including Ras. *K-ras 2A* has been identified as an aldosterone-induced gene in the rodent distal colon.[82] The glucocorticoid-induced leucine zipper protein is also aldosterone-induced; it interacts with and inhibits Raf-1, leading to repression of ERK signaling, a negative regulator of ENaC, as well as directly interacting with Sgk and Nedd 4-2.[83] A further aldosterone-induced protein, connector enhancer of kinase repressor of Ras3, appears to serve as a scaffold protein in the assembly of the ENaC regulatory complex.[74]

Na^+/K^+-ATPase

Active extrusion of sodium from the cell reflects sodium pump activity in the basolateral cell membrane. Na^+/K^+-ATPase activity is increased in epithelia by aldosterone. In toad bladder and in A6 cells, there is evidence that Na^+/K^+-ATPase α and β subunit gene expression is significantly increased in the early phase of the response to aldosterone,[61] although this does not appear to be the case in mammalian systems.[84] Na^+/K^+-ATPase activity is sensitive to intracellular sodium concentration, and in isolated cortical tubules the early Na^+/K^+-ATPase response to aldosterone is blocked by amiloride, suggesting that the increased activity is secondary to sodium influx at the apical membrane.[85] In the late phase of the aldosterone response, Na^+/K^+-ATPase mRNA, protein, and activity levels are all increased.[86] Channel-inducing factor (CHIF) was first identified as a novel corticosteroid-induced gene in the rat distal colon. CHIF is a member of the FXYD family of small transmembrane proteins, which includes the γ-subunit of Na^+/K^+-ATPase.[87] Under experimental conditions, CHIF is upregulated in the distal colon in response to aldosterone[88,89] through a primary transcriptional response. CHIF increases the affinity of Na^+/K^+-ATPase for sodium.[87] The early aldosterone-induced increase in Na^+/K^+-ATPase activity is mediated by CHIF.

Potassium Transport

Aldosterone also regulates potassium transport, independent of its effects on the electroneutral apical sodium transport coupled to the Na^+/K^+-ATPase-mediated basolateral membrane exchange of sodium for potassium. Aldosterone also increases the apical membrane channel density of renal outer medullary potassium channel (ROMK), an ATP-regulated potassium channel with weak inward rectification in the principal cells of the cortical collecting duct.[90] Sgk-1 has been reported to increase the channel density of ROMK through direct phosphorylation, through Nedd4-2,[91] or perhaps via the with-no-lysine (WNK) kinases.[92] Insights into the roles of ROMK and the channels regulated by the WNK kinases have come from studies of Bartter, Gitelman, and Gordon syndromes; however, whether the responses in the DCT are mediated via aldosterone directly or via its effects elsewhere in the nephron remains controversial. Other inwardly rectifying potassium channels expressed on the basolateral membrane act as sensors of extracellular potassium to play a central role in potassium and sodium homeostasis.[90] This aldosterone-independent pathway enables extracellular potassium to act through the type 2 mTOR complex to activate Sgk-1 and stimulate ENaC to enhance ENaC-mediated sodium transport and, indirectly, potassium excretion.[93]

The intercalated cells within the collecting duct consist of subtypes α, β, and non-α/non-β.[94] Intercalated cells express H^+-ATPase on the apical or basolateral plasma membrane, depending on whether the subtype mediates hydrogen ion or bicarbonate secretion. The β-intercalated cells express the chloride/bicarbonate ion exchanger pendrin on the apical plasma membrane and H^+-ATPase at the basolateral plasma membrane, such that increased activity will promote potassium retention. The response of the β-intercalated cell to aldosterone is modulated by phosphorylation of a specific serine (serine 843) in the LBD of the MR, which then precludes aldosterone binding.[95] Diminished plasma potassium levels promote dephosphorylation of this serine, allowing aldosterone-induced increases in both pendrin and H^+-ATPase. Dephosphorylation was also described in response to AngII; this has been suggested to provide a mechanism by which the AngII-stimulated, aldosterone-mediated response to volume depletion can result in sodium reabsorption with limited potassium depletion.

The H^+/K^+-ATPase in the apical membrane of β-intercalated cells in the collecting duct is composed of catalytic α and regulatory β subunits, with expression of the α_2 subunit being regulated by dietary potassium and corticosteroids in both the outer medullary collecting duct and the distal colon.[96]

Bartter and Gitelman syndromes are inherited conditions of hypokalemia induced by secondary aldosteronism in response to a chloride leak in the thick ascending limb and the DCT, respectively.[97] In contrast to primary aldosteronism, they are associated with hypotension rather than hypertension. The syndromes can be viewed as being pharmacologically mimicked by loop diuretics such as frusemide and thiazide diuretics, respectively. Bartter syndrome is associated with a low calcium and a normal magnesium being both uncommon and severe, whereas Giteman syndrome is associated with a normal calcium and a low magnesium, often with a milder and later onset. There are various subcategories of Bartter syndrome, but the predominant mutations are in ROMK or the sodium-potassium-chloride cotransporter, whereas mutations in the thiazide-sensitive sodium-chloride cotransporter (NCCT) (or less commonly CLCNKB—a member of CLC family of voltage-gated chloride channels) are seen in Gitleman syndrome, usually as a compound heterozygote. Gordon syndrome (pseudohypoaldosteronism type 2 or familial hyperkalemia and hypertension syndrome) can be viewed as the reciprocal phenotype of Gitleman syndrome, with low-renin hypertension, hyperkalemia, and metabolic acidosis; the condition responds to thiazide diuretics. It is a monogenic syndrome resulting from mutations in four genes, including those encoding the WNK kinases, that directly or indirectly regulate the NCCT.[98]

KEY POINTS

- Aldosterone-induced epithelial potassium and hydrogen ion transport involves sodium-dependent and -independent mechanisms.

Hydrogen Ion Transport

As for potassium, aldosterone also produces effects on proton excretion beyond a simple cation exchange for sodium across the epithelium to maintain electroneutrality. The targets for this effect are carbonic anhydrase–rich cells, particularly the α-intercalated cells within the outer medullary collecting ducts. Aldosterone-induced transport across the apical membrane is through an H+-ATPase activity, coupled with increased activity of the basolateral chloride/bicarbonate exchanger (which is upregulated by aldosterone).[99] These are largely sodium-independent effects, as demonstrated by a lack of an effect of amiloride. Aldosterone also produces an effect on the Na^+/H^+ antiporter in a range of tissues; in some tissues the response is rapid and represents a nongenomic action.[100]

NONEPITHELIAL TISSUES

The presence of the MR in a range of tissues that may not be related to electrolyte homeostasis suggests additional actions for aldosterone ion physiology and pathophysiology. In some tissues, such as the vasculature[101] and specific regions of the CNS where 11β-HSD2 is coexpressed with the MR, the MR response is likely to be attributed to activation by aldosterone. In other tissues such as cardiomyocytes and monocyte/macrophages where the MR is expressed, but 11β-HSD2 is not, rather than that of aldosterone, cortisol is the predominant ligand that activates MR, except perhaps in pathological states of aldosterone excess.[102] The MR is also expressed in a range of other tissues, including adipocytes, immune cells, and reproductive tissues, where the physiological roles remain to be determined, although in most tissues, in the absence of 11β-HSD2, they are likely to be responding to cortisol.

Cardiovascular System

In recent decades, the pathophysiology of MR in the cardiovascular systems has been defined by the use of pharmacological, genetic, and cell-selective knockout animal models to reveal cell-, ligand-, and disease-specific roles for the MR. The MR plays an important physiological role in this system to control the response to volume loss. Aldosterone-directed MR activation in the myocardium regulates the ionotropic and chronotropic activity of cardiomyocytes, resulting in increased cardiac output. MR in the vascular smooth muscle cells (VSMCs), for example, contributes to vasoconstriction, which, together with the endothelial response, has been argued to reflect aldosterone-mediated protection of vascular integrity to maintain volume homeostasis.[103] Enhanced contraction of the peripheral vasculature, via direct MR actions or via enhanced signaling of vasoactive peptides, serves to increase peripheral resistance, which, together with an increased cardiac output, will raise blood pressure and increase organ perfusion. Recent studies using transgenic mice null for the MR in VSMCs have also identified a role for the MR in vascular stiffness and blood pressure control in aging.[101]

Single-cell studies using patch-clamp to analyze single channels or ion exchangers in rabbit cardiomyocytes identified ligand-selective actions of the MR on the sodium-potassium-chloride cotransporter. Whereas acute aldosterone acutely induced flux, cortisol did not. However, under oxidative stress, cortisol was an equivalent agonist to aldosterone.[104] These studies support the increasing body of evidence that the MR in the heart has ligand-selective responses. These ligand-specific responses are important, given that the cardiac MR it is not protected by 11β-HSD2 and is thus continuously occupied by cortisol under physiological conditions.[105] Indeed, several studies have shown that cortisol can oppose aldosterone agonist effects. The question remains as to the physiological role of the MR in the heart in the absence of volume depletion and an adequate sodium/potassium intake. Very recent studies have identified the circadian molecular clock as a target of the MR in the heart and potentially in other tissues (i.e., kidney); this may represent a physiological action of the cortisol-activated MR.[106]

In the vasculature, where the MR is coexpressed with 11β-HSD2, aldosterone regulates a range of genes associated with inflammation and fibrosis, resulting in vascular remodeling. In vascular endothelial cells, chronic elevation of aldosterone increases transcription and cell surface expression of intracellular adhesion molecule-1 and vascular adhesion molecule-1 to promote recruitment of mononuclear cells as part of the profibrotic response.[103] These effects occur independent of the aforementioned increases in vascular reactivity.

In the heart (a nonepithelial tissue expressing MR), *in vivo* studies show that levels of aldosterone inappropriately high for the sodium status of the rat produce diffuse perivascular and interstitial fibrosis, an effect that can be antagonized by either corticosterone or spironolactone.[107] The clinical correlation of these observations was found in large trials showing a benefit of the addition of a mineralocorticoid antagonist to the conventional regimen in the treatment of severe cardiac failure, with respect to both morbidity and mortality.[108-110] Studies in transgenic mice using tissue-specific deletion of the MR are starting to clarify the specific roles and mechanisms of signaling through the MR in these tissues.[111]

KEY POINTS

- Activation of the MR in nonepithelial tissue is associated with a proinflammatory, profibrotic response that drives adverse cardiovascular outcome, as seen with chronic aldosterone excess.

Central Nervous System

Similarly, the MR is expressed extensively in the CNS; indeed, the hippocampus arguably has the highest abundance of MR of any tissue except for the distal colon.[28] The function of the MR in the CNS has been the subject of extensive investigation; it appears to mediate diverse behavioral responses, including memory and affect.[112] In the majority of brain regions, including the hippocampus, the MR is likely functioning as a receptor for cortisol, given that 11β-HSD2 is not coexpressed with the MR, and penetration of the blood-brain barrier by aldosterone is substantially less than that of most steroid hormones.[16] There is, however, coexpression of 11β-HSD2 and the MR in a small number of nuclei in the nucleus of the solitary tract (NTS); in these nuclei the role of the MR is to regulate salt appetite in response to aldosterone, and therefore sodium balance.[113] They occupy a subregion of the NTS with a diminished blood-brain barrier that may afford exposure to circulating aldosterone. These neurons express the AT1R, and MR activation appears to interact synergistically with AngII to promote salt appetite.[114]

SUMMARY AND FUTURE DIRECTIONS

Aldosterone acts through the MR to act as the final critical arbiter of sodium, potassium, and hydrogen ion homeostasis in the distal nephron and the distal colon. Aldosterone also promotes sodium retention, and hence volume homeostasis, through effects on salt appetite and on vascular integrity. The role of the MR in nonepithelial tissues remains to be fully elucidated, including the relative importance of cortisol and aldosterone as the physiological ligand in these tissues. The significance of progesterone as an MR antagonist in terrestrial vertebrates and as an MR agonist in fish suggests yet unappreciated roles for aldosterone and the MR.

INTRODUCTION

Glucocorticoids are primary stress hormones necessary for life that affect virtually every aspect of human physiology. They are synthesized by and released from the adrenal glands following activation of the hypothalamic-pituitary-adrenal (HPA) axis in a circadian manner and in response to physical and emotional stress. Synthetic derivatives of glucocorticoids are one of the most commonly prescribed classes of drugs in the world today.[1] The physiological actions of glucocorticoids include highly effective antiinflammatory and immunomodulatory actions that are exploited for the treatment of diseases such as asthma, arthritis, allergic rhinitis, ulcerative colitis, multiple sclerosis, and leukemia/lymphoma.[2,3] In addition, glucocorticoids have important roles in lung development, skeletal growth, behavior, reproduction, metabolism, and cardiovascular function. Ultimately, glucocorticoids act to maintain homeostasis in the face of stressful stimuli. The broad actions of glucocorticoids account for the serious side effects commonly experienced with chronic glucocorticoid treatment. These include the development of glucocorticoid resistance in diseased tissues, osteoporosis, growth retardation in children, hypertension, muscle atrophy, and metabolic syndrome.[1,4] The physiological and pharmacological actions of glucocorticoids are mediated by the glucocorticoid receptor (GR), a member of the nuclear receptor superfamily of proteins that regulate gene transcription in a ligand-dependent manner.

GLUCOCORTICOID RECEPTOR DOMAIN ORGANIZATION

Like other members of the nuclear receptor superfamily, GR is a modular protein comprised of an N-terminal transactivation domain (NTD), a central DNA-binding domain (DBD), and a C-terminal ligand-binding domain (LBD) (Fig. 89.1).[5] Separating the DBD and LBD is a flexible region of the protein termed the hinge region. The DBD is the most conserved region across the nuclear receptor superfamily. It contains two zinc finger motifs that recognize and bind target DNA sequences, termed glucocorticoid-responsive elements (GREs). The NTD is the most variable region among family members and contains a strong transcriptional activation function (AF1) that interacts with coregulators and the basal transcription machinery. The LBD forms a hydrophobic pocket for binding glucocorticoids and contains a second transcriptional activation function (AF2) that interacts with coregulators in a ligand-dependent manner. The LBD also possesses a nuclear localization signal and sites for interaction with chaperone proteins and other transcription factors. An additional nuclear localization signal spans the junction of the DBD and hinge region. The GR protein is a substrate for various types of posttranslational modifications, including phosphorylation, ubiquitination, sumoylation, and acetylation that regulate GR function (Fig. 89.1).

GLUCOCORTICOID RECEPTOR REGULATION OF TRANSCRIPTION

Unliganded GR is located in the cytoplasm of cells as part of a multiprotein complex that includes chaperone proteins (HSP90, HSP70, and P23) and immunophilins of the FK506 family (FKBP51 and FKBP52) (Fig. 89.2).[6] The chaperone proteins maintain the receptor in a transcriptionally inactive state that favors high-affinity ligand binding. Upon binding glucocorticoids, GR undergoes a conformational change resulting in the dissociation of the associated proteins, exposure of the nuclear localization signals, and translocation of the receptor into the nucleus via nuclear pores. The receptor then induces or represses gene transcription by binding directly to GREs and/or by interacting with other transcription factors and modulating their activity.

The consensus GRE sequence is an imperfect palindrome (GGAACAnnnTGTTCT) that is comprised of two 6-bp half sites separated by a three-nucleotide spacer. GR binds this element as a homodimer, with each half site occupied by one receptor subunit (Fig. 89.2A). The interaction of ligand-bound GR with the GRE results in the enhanced expression of numerous genes. For this reason, the GRE is often referred to as an activating or positive GRE. However, GR occupancy of the canonical GRE can also lead to the repression of target genes, suggesting a critical role for factors outside the GRE sequence, such as epigenetic regulators and chromatin context, in determining the polarity of the transcriptional response.[7] A negative GRE (nGRE)

Figure 89.2 **Glucocorticoid receptor (GR) signaling pathways.** The unliganded GR resides in the cytoplasm of cells in a complex with other proteins. Upon binding glucocorticoids, the receptor undergoes a change in conformation (activation), dissociates from accessory proteins, and translocates into nucleus via the nuclear pore complex (NPC). Nuclear GR regulates gene expression in three primary ways: binding directly to DNA (A), tethering itself to other DNA-bound transcription factors (B), or binding directly to DNA and interacting with neighboring DNA-bound transcription factors (C). *BTM*, Basal transcription machinery.

that differs in sequence from the classic GRE has also been described that mediates glucocorticoid-dependent repression of specific genes (Fig. 89.2A).[8] The consensus nGRE sequence, CTCC(n)$_{0\text{-}2}$GGAGA, is palindromic but has a variable spacer and is occupied by two individual GR monomers rather than a homodimer.[9] Binding sites for GR are found not only within promoters of glucocorticoid-responsive genes but also in intragenic and intergenic regions that can be far removed from the transcription start site.[10] For example, glucocorticoids have been shown to induce the expression of the β-arrestin-1 gene (*ARRB1*) via an intron 1 GRE and to repress the expression of the β-arrestin-2 gene (*ARRB2*) via an intron 11 nGRE.[11] Glucocorticoid regulation of the β-arrestin-1/β-arrestin-2 ratio alters the signaling profiles of G protein-coupled receptors and may account for the superior clinical efficacy of the glucocorticoid/beta-2-adrenergic receptor agonist combination therapies used to treat asthma and chronic obstructive pulmonary disease. Another example of clinical importance is that GR occupancy of an nGRE located in intron 6 of the *GR* gene itself mediates homologous downregulation of GR expression,[12] a mechanism of glucocorticoid resistance that limits the therapeutic response to glucocorticoids.

Many GREs are found in the genome, yet only a small fraction of these sites is actually bound by the receptor. The specific sites of

GR occupancy vary in a tissue-specific manner due to differences in chromatin landscape that regulate the accessibility of the GRE.[13] Glucocorticoid concentration can also govern GR binding to specific GREs and subsequent regulation of target gene expression.[14] For some GREs, GR occupancy occurs at very low concentrations of hormone. Other GREs, however, require high doses of glucocorticoids for GR binding to take place. Distinguishing hypersensitive from hyposensitive GREs is an important endeavor because low-dose glucocorticoid therapy targeting hypersensitive sets may avoid the harmful side effects of higher glucocorticoid doses frequently used in the clinic. The GR–GRE interaction is short-lived, as the receptor rapidly cycles on and off target sites every few seconds.[15] Upon binding DNA, GR undergoes a conformational change that leads to the recruitment of coregulators and chromatin remodeling complexes that regulate RNA polymerase II activity and thereby alter the transcription rates of target genes.[16-18] Steroid receptor coactivators (SRC1–3), the histone acetyltransferases CBP/p300, and the nuclear methylase coactivator-associated arginine methyltransferase (CARM1) are coregulators that mediate transcriptional activation, whereas nuclear receptor corepressor 1 (NCoR) and silencing mediator of retinoid and thyroid hormone receptors (SMRT) are corepressors that mediate transcriptional repression. The specific cofactors that are assembled and their activity on glucocorticoid-responsive genes depends on the ligand bound to GR, as well as the specific GRE sequence occupied by the receptor.[19,20]

In response to glucocorticoids, GR can also regulate gene expression by interacting with other transcription factors (Fig. 89.2B,C). The two most studied examples of this form of regulation involve the transcription factors activator protein 1 (AP-1) and nuclear factor-κB (NF-κB). These two proteins are central mediators of the inflammatory and immune response, and their inhibition by GR is thought to underlie the major antiinflammatory and immunosuppressive actions of glucocorticoids.[5] When activated by stress signals such as proinflammatory cytokines, bacterial and viral infectious agents, or proapoptotic stimuli, AP-1 and NF-κB bind their cognate response elements and induce the expression of many proinflammatory genes, including those encoding cytokines, cell adhesion molecules, and enzymes involved in tissue destruction. GR represses the activity of AP-1 and NF-κB through a direct interaction with the c-Jun subunit of AP-1 and the p65 subunit of NF-κB. For some genes, the inhibition is accomplished by GR tethering itself to these DNA-bound proteins without the receptor binding to DNA (Fig. 89.2B). For other genes, the repression involves GR acting in a composite manner in which the receptor both binds a GRE and physically associates with AP-1 or NF-κB bound to neighboring DNA sites (Fig. 89.2C). Glucocorticoids can also indirectly antagonize the actions of AP-1 and NF-κB by inducing the expression of antiinflammatory genes encoding factors such as IκB protein, which sequesters NF-κB in the cytoplasm,[21] MAPK phosphatase 1, which dephosphorylates c-Jun N-terminal kinase to prevent activation of AP-1,[22] and tristetraprolin, which destabilizes the mRNA of many AP-1- and NF-κB-induced genes.[23] In contrast to its repressive actions on AP-1 and NF-κB, GR interacts with specific members of the signal transducer and activator of transcription (STAT) family of transcription factors, either apart from (tethering action) or in conjunction with (composite action) GRE binding, and enhances their activity on responsive genes (Fig. 89.2B,C).[24] STAT transcription factors are activated by a range of cytokines through induction of the Janus kinase pathway (JAK) and tyrosine phosphorylation. Upon binding their cognate response elements, STATs regulate genes involved in the immune response, differentiation, survival, and apoptosis.

Global gene expression analyses indicate that up to 10% to 20% of the genome is regulated by glucocorticoids.[5] Many of these genes, termed primary glucocorticoid-responsive genes, are regulated by GR directly binding to DNA (GREs and nGREs) and/or interacting with other DNA-bound transcription factors that control the expression of the specific gene. However, GR can also have a profound influence on the genome in an indirect manner. These secondary gene changes occur more slowly and are mediated by the protein products of the primary glucocorticoid-responsive genes. This second wave of gene expression changes can be accomplished by transcription factors that are direct targets of GR regulation. For example, in the heart, glucocorticoid-activated GR increases the expression of the zinc finger DNA-binding transcription factor Kruppel like factor 13 (KLF13) via binding a GRE located in intron 1 of the *KLF13* gene. The upregulated KLF13, in turn, regulates a large cohort of genes that protect cardiomyocytes from cell death induced by the antineoplastic drug doxorubicin.[25]

KEY POINTS

- Upon glucocorticoid binding, cytoplasmic glucocorticoid receptor (GR) translocates to the nucleus.
- GR binds directly to glucocorticoid-responsive elements (GREs) or negative GREs to regulate target gene expression.
- GR also interacts with other transcription factors, such as AP-1 and NF-κB, to regulate target gene expression.

GLUCOCORTICOID RECEPTOR POLYMORPHISMS

Several polymorphisms in the *GR* gene have been described that change the amino acid sequence of the encoded receptor and alter its transcriptional activity. The single nucleotide polymorphism N363S, which results in an asparagine to serine substitution in the NTD of GR, occurs in approximately 4% of the population and is associated with glucocorticoid hypersensitivity.[26,27] N363S carriers have been reported to have an increased risk for metabolic syndrome, type 2 diabetes, decreased bone mineral density, and cardiovascular disease. Genome-wide microarrays on isolated macrophages and cultured osteosarcoma cells have revealed unique gene regulatory profiles for the N363S polymorphism compared with wild-type GR in response to glucocorticoid treatment.[28,29] The ER22/23EK polymorphism occurs in approximately 3% of the population and results in an arginine to lysine change at position 23 within the NTD of GR.[26,27] The ER22/23EK polymorphism, in contrast to N363S, exhibits reduced transcriptional activity on target genes and has been associated with glucocorticoid insensitivity. Carriers of this polymorphism have a more favorable metabolic profile due to their decreased sensitivity to glucocorticoids and exhibit a lower tendency to develop type 2 diabetes and cardiovascular disease. The mechanism underlying the glucocorticoid resistance in ER22/23EK carriers may involve alterations in the expressed complement of GR isoforms (discussed later).[30] These GR polymorphisms may account, at least in part, for the heterogeneous responses observed among individuals on glucocorticoid therapy.

GLUCOCORTICOID RECEPTOR ISOFORMS DERIVED FROM SINGLE GENE

GR is expressed throughout the body, yet there is considerable diversity among cell types in terms of their responses to glucocorticoids. The discovery of multiple GR isoforms has provided a molecular mechanism contributing to the specificity of glucocorticoid action. The human *GR* gene is located on chromosome 5q31-32 and is comprised of nine exons (Fig. 89.3). The GR NTD is encoded primarily by exon 2, the DBD is encoded by exons 3 and 4, and the hinge region and LBD are encoded by exons 5 to 9. Alternative splicing in exon 9

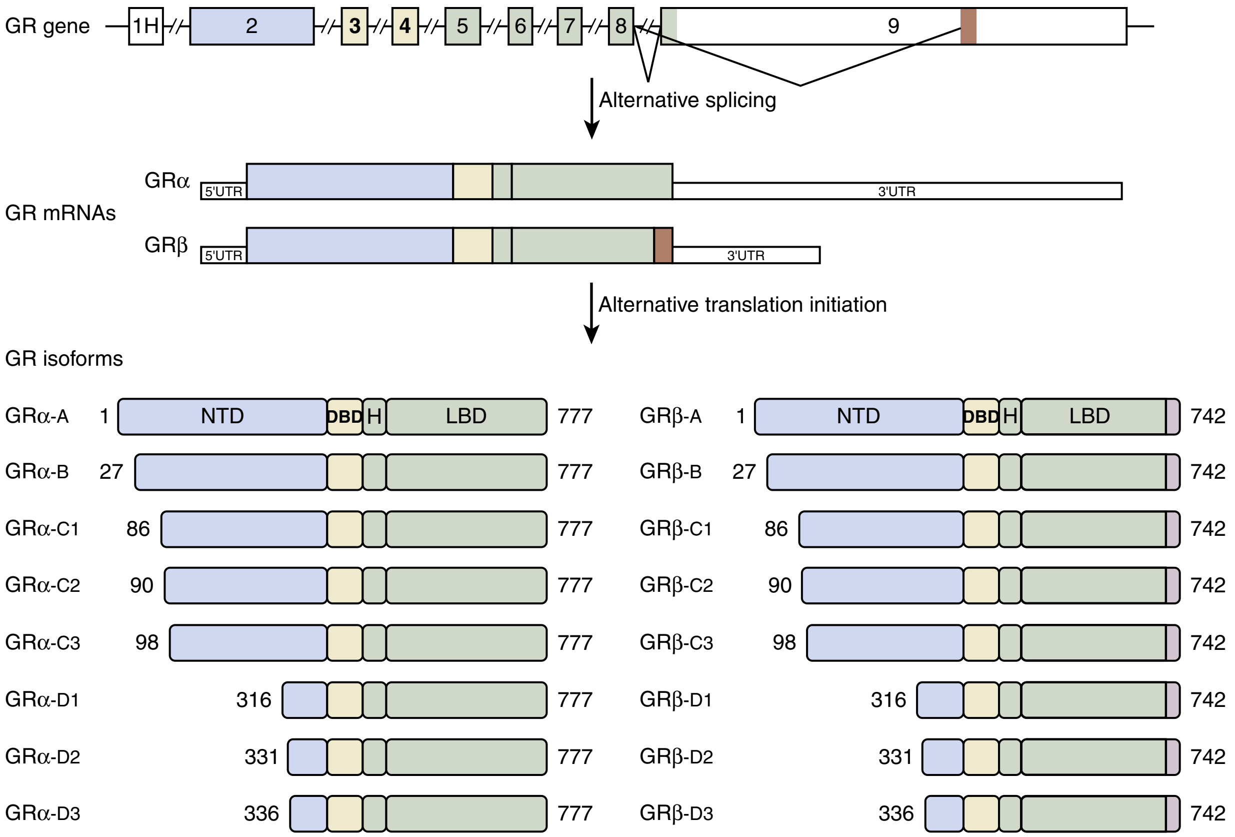

Figure 89.3 **Multiple glucocorticoid receptor (GR) isoforms generated from single gene.** The human *GR* gene is comprised of nine exons. Alternative splicing at the 3′ end of the primary transcript generates GRα and GRβ mRNAs, which encode GRα and GRβ proteins differing only at their C-terminus. Alternative translation initiation from eight different AUG start codons derived from exon 2 generates additional protein isoforms with progressively shorter N-terminal domains. Numbers shown denote the first and last residues for the human GR isoforms. For simplicity, only the most proximal of nine alternate exon 1s (1H) is shown.

generates two receptor isoforms, termed GRα and GRβ, that are identical through amino acid 727 but then diverge at their C-termini (Fig. 89.3).[5,31] The classic, full-length GRα contains an additional 50 amino acids, whereas the splice variant GRβ has an additional, nonhomologous 15 amino acids. Because of its unique C-terminus, GRβ does not bind glucocorticoids and resides constitutively in the nucleus of cells. GRβ has been shown to function as a dominant negative inhibitor and repress the transcriptional activity of GRα[32,33]; therefore, alterations in GRβ expression may contribute to changes in glucocorticoid responsiveness. Indeed, expression of GRβ is selectively increased over GRα in cells exposed to proinflammatory cytokines and microbial superantigens leading to reduced sensitivity to glucocorticoids.[5,31] Glucocorticoid-resistant forms of inflammatory diseases, such as asthma, rheumatoid arthritis, and ulcerative colitis, have also been associated with elevated expression of GRβ. Furthermore, upregulation of GRβ and diminished GRα signaling is observed in erythroid cells from patients with polycythemia vera. Conversely, methotrexate, an effective drug for treating autoimmune and inflammatory diseases, promotes a selective increase in GRα at the expense of GRβ and improves the glucocorticoid sensitivity of lymphocytes. The mechanisms underlying the dominant negative activity of GRβ are unclear but may involve competition for GRE binding and/or formation of GRα/GRβ heterodimers that are transcriptionally deficient.

The splicing factor SRp30c has been shown to play a critical role in the selective increase in GRβ expression.[34] In addition, elevated GRβ levels result from the naturally occurring ATTTA to GTTTA polymorphism (A3669G) in the 3’ untranslated region of GRβ. This nucleotide substitution disrupts an mRNA destabilization motif and leads to increased stability of the GRβ mRNA and enhanced protein expression.[35,36] Persons harboring the A3669G allele have an elevated risk for pathologies with inflammatory underpinnings, such as autoimmune disease, coronary artery disease, myocardial infarction, and heart failure, suggesting the rise in GRβ limits the beneficial immunosuppressive actions of GRα.[37-39] Another polymorphism in the GRβ 3’ untranslated region (G3134T) has also been shown to increase GRβ expression by mRNA stabilization.[40] Carriers of the G3134T polymorphism have elevated levels of endogenous glucocorticoids, display glucocorticoid resistance, and exhibit alterations in the glucocorticoid-regulated transcriptome in isolated macrophages.

A broader role for GRβ in cell signaling has recently emerged with the demonstration that this isoform can modulate gene expression apart from its effects on GRα. In a genome-wide microarray analysis performed in human osteosarcoma cells selectively expressing GRβ, the isoform was found to alter the expression of over 5000 genes.[41] Less than 20% of the genes were commonly regulated by ligand-activated GRα, indicating that GRβ possesses its own unique gene-regulatory profile. GRβ was also shown to bind the glucocorticoid antagonist mifepristone (RU486), and binding of this ligand abolished most of the GRβ-mediated changes in gene expression.[41] Interestingly, structural analysis of the GRβ/RU486 complex suggests GRβ is found in a conformation that favors corepressor binding.[42] To explore the function of GRβ *in vivo*, the splice variant was expressed in the liver of wild-type mice and in GR liver knockout mice using an adeno-associated virus.[43] GRβ antagonized the function of GRα and attenuated hepatic gluconeogenesis. Moreover, GRβ regulated many genes by GRα-independent mechanisms. For example, GRβ upregulated the expression of the *STAT1* gene in the livers of both wild-type and GR liver knockout mice. This induction involved GRβ binding to an intergenic GRE adjacent to the *STAT1* gene and was inhibited by RU486 treatment. As a *bona fide* transcription factor, GRβ may contribute to alterations in glucocorticoid responsiveness in healthy and diseased tissues by genomic effects apart from its dominant negative activity on GRα.

Alternative translation initiation of the GR mRNA produces an additional cohort of receptor subtypes (Fig. 89.3).[44,45] Eight GR translational isoforms with progressively shorter NTDs are generated from one GRα mRNA transcript via different AUG start codons: GRα-A, GRα-B, GRα-C1, GRα-C2, GRα-C3, GRα-D1, GRα-D2, and GRα-D3. The eight initiation sites are located in exon 2 and are highly conserved across species. GRα-A is the classic, full-length 777-amino acid human receptor that is generated from the first initiator AUG codon. The GRβ mRNA also contains the identical start codons and would be expected to give rise to a similar complement of subtypes.

The GRα isoforms, all of which retain an intact DBD and LBD, bind glucocorticoids with similar affinity and show a similar capacity to interact with GREs.[46] Additionally, all eight isoforms occupy the nucleus of cells following glucocorticoid treatment. In the absence of hormone, however, the subcellular distribution of the subtypes differ with the GRα-D isoforms residing predominantly in the nucleus and the others predominantly in the cytoplasm.[44,46] Marked differences have been reported in the transcriptional properties of the GRα translational isoforms.[46,47] Global microarray analysis of cells selectively expressing individual GRα isoforms revealed that each receptor subtype displays a unique gene-regulatory profile. Less than 10% of the glucocorticoid-responsive transcriptome was commonly regulated by all the isoforms, indicating that the vast majority of genes were regulated in an isoform-specific manner. The GRα-C3 isoform is the most transcriptionally active subtype, whereas GRα-D isoforms are the least active. The heightened activity of GRα-C3 has been linked to a motif in the NTD that sterically hinders the larger isoforms.[48] The isoform-unique gene-regulatory profiles were further shown to produce functional differences in cellular responsiveness to glucocorticoids, as the GRα translational isoforms exhibited distinct capabilities to induce apoptosis.[46,47] Cells expressing GRα-C3 were the most sensitive to the apoptosis-inducing actions of glucocorticoids, whereas cells expressing GRα-D3 were the most resistant. Unlike other GRα translational isoforms, GRα-D3 did not repress NF-κB activity and failed to inhibit the transcription of certain antiapoptotic genes.[49]

The GRα translational isoforms show a widespread tissue distribution; however, their relative levels vary across cell types. GRα-A and GRα-B are the most highly expressed isoforms in many cells. However, GRα-C and GRα-D are abundant in trabecular meshwork cells,[50] and the GRα-D isoform predominates in immature dendritic cells.[51] In rodents, GRα-C isoforms are expressed at high levels in the pancreas and colon, whereas GRα-D isoforms are abundant in the spleen and lungs.[44] In the human brain, the composition of GRα translational isoforms changes during development and aging.[52] Additionally, a selective increase in the GRα-D isoform has been observed in the brains from patients with schizophrenia and bipolar disorder.[53,54] Differential expression of GRα translational isoforms may be a major mechanism behind the diverse tissue sensitivity and responses to glucocorticoids. *In vivo* support for this conclusion comes from knockin mice that exclusively express the GRα-C3 isoform.[55] The GRα-C3 knockin mice die at birth due to respiratory distress but can be rescued by antenatal glucocorticoid administration. Rescued GRα-C3 mice exhibited alterations in sensitivity to lipopolysaccharide (LPS)-induced inflammation, and gene expression studies revealed a deficiency in the ability of GRα-C3 to regulate a large cohort of immune and inflammatory response genes in the spleen.

KEY POINTS

- The single glucocorticoid receptor (GR) gene gives rise to multiple protein isoforms.
- Alternative slicing in exon 9 of the GR gene produces the GRβ splice variant.
- Alternative translation initiation of the GR mRNA produces eight GRα translational isoforms with progressively shorter N-terminal domains.
- The various GR isoforms, with their unique expression and gene-regulatory profiles, contribute to tissue specificity in glucocorticoid responsiveness.

GLUCOCORTICOID RECEPTOR POSTTRANSLATIONAL MODIFICATIONS

In addition to the diversity in cellular response to glucocorticoids driven by changes in the coding sequence of GR (i.e., via polymorphisms, splicing, or translational isoforms), posttranslational modifications to the receptor can have a profound effect on glucocorticoid-regulated transcription.[56-59] Phosphorylation is the most well characterized, but not the only, posttranslational modification of GR and was initially described in the mid-1970s. It was proven to occur in the late 1980s and early 1990s with the identification of specific phosphorylated amino acid residues within the receptor. The application of sophisticated mass spectrometry methods and assessment of distinct model systems have led to more recent identification of new GR phosphorylation sites previously unrecognized. Currently, 16 highly conserved amino acids within the GR (15 within the amino terminal domain and one within the hinge region) have been shown to be phosphorylated, with 15/16 occurring within serine and/or threonine residues and only one at a tyrosine residue. Many of the GR phosphorylation sites are regulated by ligand binding to the receptor, with two recently identified phosphorylation sites induced by brain-derived neurotrophic factor (BDNF).

Studies using pharmacological approaches to modulate GR phosphorylation first pointed to a role for site-specific GR phosphorylation in directing distinct transcriptional responses of the receptor. The application of site-directed mutagenesis, as well as biochemical and genomic approaches, revealed the mechanistic basis for distinct transcriptional responses directed by GR with site-specific phosphorylation. Thus, each phosphorylation site on GR presents a unique surface that impacts the binding affinity of a wide variety of cofactors.[60-62] These selective phospho-GR/cofactor complexes are likely to be differentially stabilized at direct or indirect GR binding sites on the genome, ultimately leading to selective modulation of transcriptional output from linked glucocorticoid-responsive promoters. Furthermore, this modulation of GR transcriptional activity will be responsive to many physiological signals or drugs that impact the activity of intracellular protein kinases and phosphatases that directly act on the receptor. For example, long-acting beta-2-adrenergic agonists, which are used in combination with inhaled corticosteroids to treat moderate or serve persistent asthma, may enhance the antiinflammatory effects of glucocorticoids through modulation of site-specific GR phosphorylation.[63,64]

In many cases, site-directed mutagenesis has confirmed the biological effects of specific GR phosphorylation sites. For example, GR phosphorylation at serine 134 is elevated in triple negative breast cancer

(TNBC) relative to other breast cancers.[65] Furthermore, *in vitro* experiments with TNBC cells established the role for serine 134 phosphorylation in the migratory, invasive, and stem cell properties of these cells, demonstrating that GR phosphorylated at serine 134 generates a unique transcriptome. The relevance of these *in vitro* results was suggested from analysis of gene expression profiles of breast cancer patient samples, which reveal poorer survival outcomes in those stratified patients with relatively higher expression levels of the GR phosphoserine-134 gene signature. In mice, BDNF-regulated GR phosphorylation plays a role in the retention of newly learned motor skills through a mechanism that involves the stabilization of newly formed postsynaptic dendritic spines in the motor cortex.[66] The impact of BDNF on multiple brain circuits regulating resilience to stress could be driven in part by regulation of specific GR phosphorylation events.[59] Assessment of site-specific phosphorylation of GR may be a useful clinical biomarker for diseases influenced by altered GC signaling, as evidenced by studies associating changes in site-specific receptor phosphorylation with severe asthma[67] and type 2 diabetes.[68]

In addition to dynamic changes in GR phosphorylation in response to physiologic or therapeutic inputs, receptor phosphorylation is also likely influenced by cell- and tissue-specific factors. GR phosphorylation is prominent in the central nervous system,[69] and many studies in animal models have identified site-specific modulations of receptor phosphorylation within select brain regions in response to acute and chronic insults or various types of stress.[70-72] Some of the same GR phosphorylation sites implicated in rodent stress responses are altered in peripheral blood mononuclear cells (PBMCs) of humans with neuropsychiatric conditions, in some cases in a sex-specific manner.[73,74] Thus, a comprehensive analysis of GR phosphorylation in PBMCs may provide some insights into changes in GC signaling in the brain that are associated with select neuropsychiatric disorders.

Other posttranslational modifications in addition to phosphorylation have been shown to modulate GR function. Degradation of the GR through the ubiquitin-proteasome pathway requires modification of a specific receptor lysine residue (lysine 419 in human GR) by ubiquitin.[75] This posttranslational modification involves the concerted action of three specific enzymes culminating in the covalent addition of the 79-amino acid ubiquitin moiety on GR by an E3 ligase enzyme. A number of E3 ubiquitin ligases have been identified that catalyze the ubiquitylation and subsequent degradation of GR,[76-78] and in some cases, the signaling pathways that regulate GR ubiquitylation and turnover have been identified and biological effects revealed.[79] Small ubiquitin-like modifiers are small proteins that are also covalently attached to GR using an analogous multienzyme pathway related to the ubiquitin pathway. However, rather than target the receptor for degradation, sumoylation of GR influences its promoter-specific transcriptional regulatory activity.[80-82] Finally, GR has been shown to be subjected to nitration[83] and acetylation,[84,85] which may regulate the receptor's action in antiinflammatory and circadian pathways, respectively.

KEY POINTS

- Posttranslational modifications of glucocorticoid receptor (GR) include phosphorylation, ubiquitination, sumoylation, nitration, and acetylation.
- Site-specific phosphorylation of GR directs unique transcriptional responses by regulating the receptor's interaction with various cofactors.
- Site-specific phosphorylation of GR has specific physiological and pathological effects.
- Site-specific ubiquitination of GR alters the degradation properties of the receptor.

GLUCOCORTICOID RECEPTOR PHYSIOLOGY

Glucocorticoids have major effects on the organ systems of the body. Understanding the physiological actions of glucocorticoids has been aided by the development of novel mouse strains with conditional knockout of GR in specific cell types.[86] The following sections summarize recent progress elucidating the role of glucocorticoids and GR signaling in the immune system, cardiovascular system, central nervous system, and metabolism.

Immune System

Proper modulation of immune system activity and inflammation is critical to normal human function. A blunted immune response leaves the door open for potentially fatal infections, whereas an overstimulated immune response can result in autoimmune activity that damages organs. Glucocorticoids are widely used in the clinic for their ability to suppress the immune system and inhibit inflammation.[87,88] The glucocorticoid-mediated immunosuppression impacts both the innate and adaptive immune response and involves multiple mechanisms, including the stimulation of antiinflammatory genes, repression of proinflammatory genes (primarily by inhibiting NF-κB and AP-1 activity), and regulation of genes involved in apoptosis. The innate immune system is the first line of defense in response to pathogen or injury and is mediated by leukocytes, macrophages, and dendritic cells, among others. The adaptive immune response is a second line of defense mediated by T and B lymphocytes. Glucocorticoids achieve their immunosuppressive effects by acting on nearly all cell types of the immune system.

Macrophages play a central role in innate immunity via the expression of pattern recognition receptors that sense infectious agents and harmful signals. This leads to activation of the inflammasome complex and the release of proinflammatory cytokines. GR signaling has been shown to suppress the immune response in macrophages as mice lacking GR specifically in macrophages exhibit greater mortality and increased cytokine production in response to LPS than wild-type mice.[89] A critical role for macrophage GR in the downregulation of inflammatory cytokines and chemokines in contact dermatitis has also been demonstrated in macrophage GR knockout mice.[90] Interestingly, glucocorticoids have also been shown to augment the proinflammatory response in macrophages by inducing expression of inflammasome components and specific Toll-like receptors and by promoting macrophage migration via the upregulation of exopeptidase dipeptidyl peptidase-4.[88,91] Thus, macrophage GR signaling may function initially to prime the immune system to respond to injury and then subsequently to limit the inflammatory response and restore homeostasis.

Dendritic cells are antigen-presenting cells that coordinate both innate and adaptive immunity. Glucocorticoids suppress the maturation and migration of dendritic cells and stimulate their death by apoptosis.[92] Mice lacking GR in dendritic cells have revealed that glucocorticoids protect against LPS-induced sepsis by suppressing the expression of the proinflammatory cytokine IL-12 by dendritic cells.[93]

Proinflammatory T-cells of the adaptive immune response undergo apoptosis in response to glucocorticoids.[92] Mice with conditional knockout of GR in T-cells have revealed that glucocorticoid signaling limits potentially lethal cytokine production by T-cells in response to immune activation.[94] In addition, studies on T-cell-specific GR-deficient mice have shown that the beneficial actions of glucocorticoids in models of rheumatoid arthritis, multiple sclerosis, sepsis, and helminth infection are mediated by GR signaling events that inhibit T-cell function, alter T-cell migration, and/or lead to thymocyte cell death.[95-99] Furthermore, it has been demonstrated in these conditional knockout mice that GR signaling promotes T-cell selection.[100] The function of B-cells is also modulated by glucocorticoids. Glucocorticoids regulate B-cell activation, survival, proliferation, and differentiation.[101] Moreover, it was recently demonstrated in mice with B-cell–specific deletion of GR that glucocorticoid signaling is required for proper migration of mature B-cells from blood to bone marrow.[102]

Many immune genes are regulated by GR in a sex-specific manner.[103] In rats, glucocorticoids were shown to regulate a greater number of inflammatory genes and elicit a greater antiinflammatory response in males compared with females.[104] Sexual dimorphism in the immunosuppressive actions of glucocorticoids not only provides a mechanistic basis for the predisposition of females to develop autoimmune diseases but also suggests that glucocorticoid dosages used in the clinic should be optimized based on the sex of the patient.

Cardiovascular System

Glucocorticoids can have both positive and negative effects on the heart.[105] The contractile performance of the heart is improved by glucocorticoid treatment, and cardiomyocyte cell death triggered by various insults can be blocked by glucocorticoids. However, elevated glucocorticoids can also lead to bradycardia, cardiac hypertrophy, and heart failure. Moreover, major risk factors for cardiovascular disease, including metabolic syndrome and hypertension, are associated with increased levels of glucocorticoids. Differences in physiological context and the magnitude and duration of the glucocorticoid exposure likely play a role in whether the actions of glucocorticoids on the cardiovascular system are beneficial or adverse. The cardiovascular outcomes may also depend on whether glucocorticoids are acting directly on the heart or indirectly via their systemic effects on blood pressure and metabolism.

New insights into the direct actions that glucocorticoids have on the heart have come from transgenic mouse models with altered expression of GR in cardiomyocytes.[105] Mice overexpressing GR in cardiomyocytes have conduction defects, including bradycardia and atrioventricular block.[106] Prenatal studies performed on mice with global knockout of GR or selective knockout of GR in cardiomyocytes revealed a critical role for GR in the maturation of the fetal heart.[107,108] Glucocorticoid signaling in fetal cardiomyocytes was necessary to maintain appropriate expression levels of genes important for cardiomyocyte architecture and function. Using adult mice bearing a conditional deletion of GR in cardiomyocytes, several laboratories have demonstrated that GR signaling is required for normal heart physiology and function.[109-111] Mice lacking cardiomyocyte GR spontaneously develop heart disease characterized by pathological cardiac hypertrophy, left ventricular systolic dysfunction, heart dilatation, and fibrosis, and these knockout mice die prematurely from heart failure. Mechanistically, the absence of cardiomyocyte GR signaling leads to the dysregulation of key genes involved in calcium handling. Interestingly, cardiomyocyte GR has been shown to act in a sexually dimorphic manner, as male mice lacking the receptor were more sensitive to heart disease than their female counterparts.[112] In addition, deleterious signaling by the closely related mineralocorticoid receptor (MR), which can be bound and activated by glucocorticoids, was found to exacerbate the pathology in hearts lacking GR, suggesting that balanced cardiomyocyte GR and MR signaling is critical for normal heart homeostasis.[109]

Central Nervous System

Receptors for glucocorticoids are widely expressed in the central nervous system (CNS) and thereby influence various behaviors, emotional responses, learning and memory, and central control of metabolic and autonomic function. The expression of MR, which is activated by basal levels of natural glucocorticoids, such as cortisol in humans, is much more restricted in the brain than GR and is limited primarily to structures within the limbic system (i.e., hippocampus, amygdala, and prefrontal cortex).[113] Furthermore, MR is responsive to cortisol in the brain, because it lacks 11β-hydroxysteroid dehydrogenase-2, the cortisol inactivating enzyme highly expressed in kidney that blocks MR activation by cortisol in kidney. Extensive studies in humans and animal models established a role for MR in various aspects of memory and executive function, as well as cognitive responses to stress.[114] Both genomic[115] and nongenomic[116] actions of MR are likely to mediate its complex regulation of memory, cognition, and emotional state and driven by dynamic changes in connectivity and neurotransmission that accompany a central response to an emerging stress. As GRs are also eventually engaged in the central response to stress, the dynamic shift from MR- to GR-driven outputs[117] aids in the recognition, processing, and response to variable stresses that is adaptive. Chronic stress, long-term exposure to synthetic glucocorticoids, or disruption of the ultradian and/or circadian rhythm of endogenous glucocorticoid accumulation can alter the dynamic balance between MR and GR signaling in the CNS, leading to maladaptive responses to stress that can contribute to affective disorders.[118]

GRs in the CNS regulate behavior, cognition, and affective functions; however, they also control energy metabolism,[119] acting through specific neuroendocrine cells within the hypothalamus.[120] Regulation of the HPA axis is another function of central GRs, although negative feedback of adrenal glucocorticoid synthesis and secretion also operates at the level of corticotrophs within the anterior pituitary. Glucocorticoid suppression of corticotrophin-releasing hormone (CRH) synthesis and release from neuroendocrine cells within the paraventricular nucleus in the hypothalamus involves numerous pathways and circuits regulated directly and indirectly by central GRs.[121] In the paraventricular nucleus (PVN), rapid inhibition of CRH release is due to glucocorticoids acting indirectly via a nongenomic mechanism to reduce glutamatergic drive to CRH neurons.[121] Specifically, activation of classical GR located within the plasma membrane stimulates the production of endocannabinoids, which act on cannabinoid receptor type 1 within presynaptic terminals that synapse onto CRH neurons to reduce glutamate release.[122,123] As in other examples of nongenomic glucocorticoid actions in the brain,[124] rapid stimulation of endocannabinoid production by glucocorticoids require nuclear GR localized at the plasma membrane.[125] Multiple intracellular pathways are activated by ligand-bound plasma membrane-associated nuclear GR, although mobilization of intracellular calcium stores is one of the more prominent features of rapid GR signaling in neuronal systems.[124,126] In contrast to the inhibitory effects of nongenomic GR signaling on neurotransmission in the PVN, stress-induced activation of plasma membrane GR and MR via glucocorticoids in limbic areas increases glutamate release and is likely driven by intracellular signaling pathways distinct from those that modulate glucocorticoid effects on endocannabinoid production.[127,128]

The completion of central negative feedback control of the HPA axis requires GR action within limbic structures, including the prefrontal cortex and hippocampus.[121,129] While the importance of "delayed feedback" from limbic areas to regulate HPA axis function had been recognized for many years based upon lesion and pharmacologic studies,[129,130] identification of the specific regions and cell types that utilize transcriptional responses of GR to modulate inhibitory inputs into CRH neurons was firmly established using mouse models with cell type–specific deletions of the receptor.[86,131,132]

Hepatic Carbohydrate and Lipid Metabolism

Glucocorticoid effects on carbohydrate and lipid metabolism are widely recognized.[133-135] The homeostatic effects of these hormones on systemic metabolism are due to their promotion of gluconeogenesis in the liver and the mobilization of substrates in peripheral tissues, such as white adipose and skeletal muscle. They also limit glucose update in peripheral tissues and promote glycogen storage in liver. Glucocorticoids also promote gluconeogenesis and lipid metabolism through "permissive" effects on other hormones, including glucagon and catecholamines.[133-135]

The mechanisms responsible for glucocorticoid stimulation of gluconeogenesis in liver have been extensively studied and rely primarily, but not exclusively, on the transcriptional induction by GR of many genes in the gluconeogenic pathway.[135,136] This transcriptional response is essential to physiologic regulation of glucose homeostasis, as evidenced by hypoglycemia caused by adrenal insufficiency. Much of the current understanding of the molecular mechanisms responsible for hepatocyte-specific transcriptional regulation of gluconeogenesis comes from extensive molecular studies of the phosphoenolpyruvate carboxykinase (*PCK1*) gene, which revealed one of the earliest examples of "composite" GREs that include GR and other tissue- or cell type–enriched transcription factors required for a functional glucocorticoid response.[136-138] Members of the forkhead box transcriptional factor family play a prominent role in both glucocorticoid and insulin regulation of many genes in the gluconeogenesis pathway in hepatocytes.[135,139-141]

In mouse liver the C/EBPβ protein is required to "preprogram" chromatin accessible sites to allow for GR binding and an ensuing transcriptional response.[142] However, this is only one level of complexity in GR regulation of gluconeogenesis, as the dynamics of GR cooperation with other transcription factors can change in response to the duration of a fasting state.[143] Specifically, during a short-term fast, GR enhances the recruitment of the cyclic AMP response element-binding protein 1 (CREB1) transcription factor to gluconeogenic gene enhancers, leading to synergistic activation of transcription initially mobilized following glucagon-induced site-specific phosphorylation and activation of CREB1.[144] In contrast, in response to a long-term fast, GR promotes the transcription of ketogenic and fatty acid oxidation pathway genes through the induction of a major regulator of these pathways, the peroxisome proliferator-activated receptor alpha (PPARα).[144]

Glucocorticoids also regulate lipogenesis in hepatocytes and increase triglyceride levels primarily through the inhibition of lipolysis and induction of triglyceride synthesis.[136,145] The impact of glucocorticoids on lipid metabolism in the liver is not limited to direct action of the GR on genes in the lipogenesis pathway, as other signaling pathways affecting glucose metabolism and insulin sensitivity influence the effect of glucocorticoids on lipid metabolism.[136,143,146] For example, the gene encoding the transcriptional repressor Hes1 is a direct GR target gene, and repression of its transcription by glucocorticoids is essential not only for the regulation of lipid metabolism in hepatocytes,[147] but also for many systemic responses to glucocorticoids.[148]

GLUCOCORTICOID RECEPTOR LIGANDS AND PULSATILITY

The physiological response to glucocorticoids occurs in the context of their rhythmic production and secretion from the adrenal gland. Specifically, superimposed upon the daily fluctuations in circulating glucocorticoid levels, which peaks in the early morning and reaches its nadir around midnight in humans, are ultradian rhythms of glucocorticoid secretion that have a periodicity of 60 to 90 minutes.[149] Different physiological pathways underlie the complex regulation of daily versus ultradian rhythms of circulating glucocorticoids, with circadian pacemakers in the hypothalamus predominantly regulating the daily rhythm of glucocorticoid secretion from the adrenal, while ultradian rhythms are mediated by the balance between feedforward control of adrenal glucocorticoid production by pituitary ACTH and negative feedback by glucocorticoids on ACTH production.[150] Various approaches have been used in animal models to reveal an impact of altered glucocorticoid rhythms on metabolism, inflammation, and multiple behavioral outcomes. Alterations in the daily rhythms of glucocorticoids modulate their action on regulators of circadian rhythms (e.g., PER and REV-ERBA) in peripheral organs contributing to disruptions in carbohydrate and lipid metabolism.[151,152] In humans, chronic elevations of endogenous or exogenous glucocorticoids in Cushing syndrome trigger high morbidity and mortality associated with pathophysiological effects on metabolism, cardiovascular function, immune responses, and behavior.[149] These adverse effects may be exacerbated by alterations in circadian clock gene expression, which coordinate many external outputs to optimize systemic metabolic activity. This has led to glucocorticoid replacement therapy regimens for patients with adrenal insufficiency that mimic the natural daily and ultradian rhythm of glucocorticoid secretion (i.e., "chronopharmacotherapy"), which have demonstrated clinical benefit.[153] Molecular changes in cellular response to glucocorticoid chronotherapy have also been reported. Specifically, analysis of peripheral blood mononuclear cells from patients in the Dual Release Hydrocortisone versus Conventional Glucocorticoid Replacement Treatment in Hypocortisolism (DREAM) trial revealed physiological patterns of *CLOCK* gene expression by modified release hydrocortisone but not conventional multiple daily doses.[154] Modified release patients also had better body weight reduction, normal immune profiles, and improved quality of life. Furthermore, in healthy subjects with pharmacological suppression of glucocorticoid synthesis, the restoration of normal daily and ultradian rhythms of cortisol was most effective at maintaining positive mood and "resting state neural dynamics," as revealed by functional neuroimaging.[155] Finally, the administration of synthetic glucocorticoids (i.e., two daily doses 24 hours apart) to pregnant women "out of phase" with their natural daily rhythm of circulating cortisol can have long-lasting effects on the stress responsivity of their infants at 5 years of age.[156] Therefore, glucocorticoid chronotherapy that takes into account the natural rhythm of cortisol may have long-lasting clinical benefit in patients requiring chronic or even acute glucocorticoid treatment.

How do the patterns of glucocorticoid rhythms affect the cellular response of the GR? Synthetic glucocorticoids used therapeutically typically exhibit a higher affinity for GR than cortisol and dissociate much more slowly from the receptor. These differences in the kinetics of ligand occupancy of the receptor modulate the dynamics of GR binding to specific target sites in the genome. Cycles of GR occupancy on target genes are further modified by ATP and chaperone proteins operating in the nucleus.[157,158] At the molecular level, the dynamics of GR binding to genomic sites in cells occurs at a much more rapid time scale (i.e., seconds) than ultradian pulses of natural glucocorticoids.[15] This inherent property of the GR and other transcription factors may aid in the stochastic sampling of preassembled macromolecular complexes within the genome and facilitate the selectivity of transcriptional responses of the receptor. Finally, dynamic chromatin occupancy of the GR in cells and animal models driven by pulsatile exposure to natural glucocorticoids that mimic ultradian rhythms can impact gene-specific responses to glucocorticoids.[159] Therefore, enhanced clinical efficacy of glucocorticoid chronotherapy may be driven by natural cycles in the genomic structure and organization of GR-responsive genes that require the appropriate assembly of receptor-interacting factors for an efficient transcriptional response to glucocorticoid exposure.

KEY POINTS

- Glucocorticoids are secreted by the adrenal gland in circadian and ultradian rhythms.
- Glucocorticoid chronotherapy that mimics the natural rhythm of circulating cortisol has demonstrated clinical benefit.

GLUCOCORTICOID RECEPTOR RESISTANCE

Generalized glucocorticoid resistance (GGR) or "Chrousos syndrome" is a rare disorder characterized by ACTH-dependent hypercortisolism and the absence of clinical features of glucocorticoid excess.[160,161] The glucocorticoid sensitivity of all tissues is decreased in GGR. Physiologically normal serum cortisol concentrations are therefore insufficient to suppress CRH and ACTH secretion from the hypothalamus and anterior pituitary, respectively. Consequently, ACTH levels are elevated and stimulate the adrenal glands to produce greater than normal amounts of cortisol, adrenal androgens, and mineralocorticoids. In GGR, glucocorticoid resistance extends to peripheral tissues, although sensitivity to androgens and mineralocorticoids is normal. Hence, the clinical findings are not those of glucocorticoid excess, but rather those of mineralocorticoid excess (hypertension and hypokalemia) or hyperandrogenism. Treatment of Chrousos syndrome consists of suppressing the excess ACTH secretion through administration of mineralocorticoid-sparing glucocorticoids such as dexamethasone.

Loss of function mutations within the *GR* gene have been identified in a majority of individuals with GGR, with the LBD as the most common site of mutation.[161,162] While many LBD mutations in GGR reduce hormone-binding affinity, the transcriptional regulatory activity of GR can also be affected by LBD mutations that do not impact ligand binding.[163] Loss-of-function mutations have also been found in other GR domains in GGR individuals leading to reduced DNA binding, nuclear translocation, or expression.[161] In some individuals with GGR, *GR* gene mutations have not been identified, suggesting that other components of the glucocorticoid signaling pathway in GGR may be uniquely sensitive to specific gene mutations that do not affect other endocrine systems.[164,165]

Acquired glucocorticoid resistance is much more common than GGR and is often characterized by tissue-selective resistance of GR to endogenous or synthetic glucocorticoids.[166] This form of resistance is often associated with chronic inflammatory conditions,[167,168] corticotropinomas,[169,170] or hematological malignancies.[166,171] This resistance reduces the therapeutic benefit of glucocorticoids to treat leukemia, lymphoma, and myeloma, as well as many chronic inflammatory conditions. Although uncommon, somatic GR mutations have been identified that are responsible for malignant cell resistance to glucocorticoid therapy, although they are not associated with GGR, as expected from their somatic origin.[166] More common mechanisms responsible for glucocorticoid resistance in malignant cells are reductions in GR expression and the generation of alternative GR mRNA splice isoforms, such as GRβ discussed earlier. Recently, genome-wide analysis identified novel genes and pathways contributing to glucocorticoid resistance in acute lymphoblastic leukemia.[172] Such comprehensive genomic analysis of glucocorticoid resistance is likely to generate novel therapeutic strategies and drug combinations that could mitigate malignant cell resistance to glucocorticoid therapy.[172]

Most severe asthma patients do not respond well to glucocorticoid treatment and are designated as having glucocorticoid-unresponsive, refractory, or resistant asthma.[173-175] The molecular basis of glucocorticoid-resistant asthma has been extensively studied, revealing several molecular and cellular mechanisms that may contribute to the failure of this typically highly effective class of agents to control asthma symptoms and exacerbations.[168,173,175] Mutations or polymorphisms within the *GR* gene are unlikely to be a major contributor to glucocorticoid-resistant asthma, although some rare cases in specific ethnic populations may exist.[176] However, genome-wide association studies have identified a functional variant in a glucocorticoid-regulated gene (i.e., the glucocorticoid-induced transcript 1) that is associated with reduced lung function response to inhaled glucocorticoids.[177] Additional rare genetic variants that contribute to the development of glucocorticoid-resistant asthma may be uncovered with more extensive pharmacogenetic and pharmacogenomic analyses in distinct populations.[178]

As mentioned earlier for other forms of glucocorticoid resistance, an increase in the GRβ/GRα ratio plays a significant role in glucocorticoid-resistant asthma.[179-182] The induction of *GRβ* gene expression in airway epithelial cells that could generate glucocorticoid resistance is promoted by specific T-helper-type 17 cytokines.[183,184] Activation of the p38 mitogen-activated protein kinase (MAPK) by proinflammatory cytokines is one intracellular pathway that contributes to upregulation of GRβ expression and the development of glucocorticoid-resistant asthma.[185,186] The impact of proinflammatory cytokines and activated MAPK pathways on glucocorticoid-resistant asthma are not limited to the regulation of GRβ expression and extend to inhibitory effects on various components of the GRα intracellular signaling, including DNA binding,[187] nuclear translocation,[188] and interaction with transcription factor or coregulator partners.[187,189,190] Some of these effects may be mediated by direct posttranslational modification of GRα (e.g., phosphorylation[191]) or alterations in receptor or partner protein oxidation as a result of oxidative or nitrative stress.[192]

KEY POINTS

- Generalized glucocorticoid resistance affects all tissues and is most often caused by mutations in the glucocorticoid receptor (GR) ligand-binding domain, resulting in reduced hormone-binding affinity.
- Acquired glucocorticoid resistance is tissue-specific and is commonly caused by reductions in GR expression and/or increased expression of the dominant-negative splice variant GRβ.

SUMMARY AND FUTURE DIRECTIONS

Glucocorticoids act through GR to regulate numerous physiological processes, and synthetic derivatives of these hormones are widely prescribed for their antiinflammatory and immunosuppressive actions. Tissue responses to glucocorticoids are markedly different, and this heterogeneity in glucocorticoid signaling presents a challenge to clinicians in managing patients on glucocorticoid therapy. The diversity in glucocorticoid signaling is achieved by multiple processes, including polymorphisms in the *GR* gene, the generation of various GR isoforms by alternative splicing and alternative translation initiation, and posttranslational modifications of the receptor protein. The capacity of a cell to generate dozens of GR isoforms with unique gene-regulatory profiles provides enormous potential for variations in GR signaling. Moreover, the glucocorticoid response is impacted by the glucocorticoid secretion rhythm and by both general and acquired glucocorticoid resistance. A critical goal of future studies will be to use genetic approaches to assess the contribution that an individual GR isoform makes to the actions of glucocorticoids in the whole animal. Additionally, it will be important to determine whether changes in the tissue complement of GR isoforms underlie pathologies characterized by glucocorticoid resistance and/or the severe side effects that accompany glucocorticoid treatment. Finally, it will be crucial to determine the transcriptome for individual GR isoforms and to assess how it changes in response to receptor posttranslational modifications. A greater understanding of the factors and molecular processes that control tissue-specific responses to glucocorticoids should aid in the development of safer and more effective glucocorticoid therapies.

ADRENARCHE

The morphologic and functional characteristics of the adrenal glands change dramatically through the different stages of prenatal and postnatal development. *Adrenarche* is defined as the increased production of dehydroepiandrosterone (DHEA) and dehydroepiandrosterone sulfate (DHEAS) by the zona reticularis of the adrenal glands between 6 and 8 years of age. However, with newer data indicating that urinary excretion of DHEA and its metabolites begins to increase at as early as 3 years of age, the age at onset of adrenarche is being reexamined.[1]

The phenomenon of adrenarche is observed in humans and some nonhuman primates. Current data suggest that the great apes and other nonhuman primates may also experience adrenarche. Yet, sustained postnatal increased DHEAS concentrations are limited to humans, chimpanzees, and bonobos.[2,3] It has been speculated that one function of adrenarche is to modify the neural, behavioral, and psychosocial development as part of the human transition from child to adult.[4] Clarifying the physiologic roles of the C19 adrenal steroid hormones, especially DHEAS, during adulthood is an ongoing process. Investigating the mechanisms regulating changes in DHEA and DHEAS production will improve understanding of zona reticularis function in health and disease.

KEY POINTS

- *Adrenarche* is defined as the rise in adrenal androgens that occurs in mid-childhood and is responsible for the appearance of pubic hair.
- The term "adrenal androgens" refers to 19-carbon steroids (C19 steroids) including dehydroepiandrosterone, dehydroepiandrosterone sulfate, and androstenedione. These steroids do not bind to the androgen receptor. Rather, these steroids are converted to more potent sex steroids.

THE ADRENAL GLANDS

The adrenal cortex synthesizes and secretes diverse C21 and C19 steroid hormones beginning *in utero* and ending with the demise of the individual. The Italian anatomist and physician Bartolomeo Eustachio was the first to describe and provide anatomic depictions of the adrenal glands, in 1543.[5] Approximately 300 years later, Thomas Addison described the phenotype associated with adrenal insufficiency.[6] Subsequently, Charles Edouard Brown-Séquard confirmed the importance of the adrenal glands; he demonstrated that bilateral adrenalectomy led to rapid death attributed to loss of vital hormones.[7] In 1950, the Nobel Prize in Physiology and Medicine was awarded to Edward Calvin Kendall, Tadeusz Reichstein, and Philip Showalter Hench for their discoveries of the adrenal cortical hormones and their biological effects.

THE FETAL ADRENAL GLAND

The adrenal glands consist of two separate components, the cortex and the medulla, which have distinct embryonic origins. In the human fetus, the cortex develops around 28 to 30 days postconception from cells in the intermediate mesoderm located between the coelomic epithelium and the dorsal aorta. These cells develop into the adrenogonadal primordium. Around 32 to 40 days postconception, the adrenogonadal primordium separates. Cells that migrate retroperitoneally to the cranial pole of the mesonephros develop into the adrenal primordium. Subsequently, neural crest derived cells invade the adrenal primordium; these cells develop into the catecholamine secreting chromaffin cells of the adrenal medulla.[8]

An outer mesenchymal capsule surrounds the entire adrenal gland. In the fetus, two distinct concentric zones, the outer definitive and inner fetal zones, can be identified. Beginning at approximately 8 weeks of gestation, the fetal adrenal is an active endocrine organ. The clear demarcation in adrenal weights for normal infants compared to those with anencephaly and congenital adrenal hyperplasia highlights the important role of adrenocorticotropic hormone (ACTH) as a tropic factor influencing the growth of the fetal adrenal gland (Fig. 90.1).[9]

Due to minimal CYP17A1 activity, the human placenta cannot synthesize estrogen *de novo*. Hence, one major activity of the human

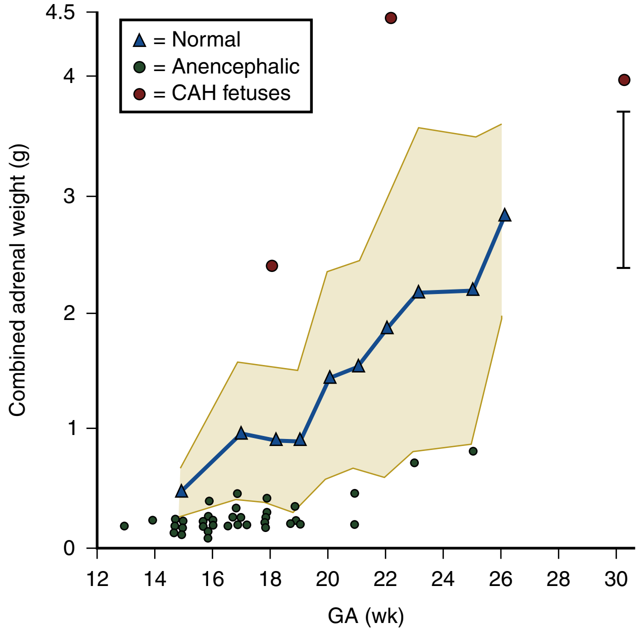

Figure 90.1 **Combined fetal adrenal weights according to gestational age.** *CAH*, Congenital adrenal hyperplasia; *GA*, gestational age. (Data from Young MC, Laurence KM, Hughes IA. Relationship between fetal adrenal morphology and anterior pituitary function, *Horm Res*. 1989;32:130–135.)

fetal adrenal is to provide substrates to the placenta, with its robust aromatase activity, for estrogen biosynthesis. During a brief period at around 8 to 12 weeks of gestation, the enzyme 3β hydroxysteroid dehydrogenase type 2 (HSD3B2) is expressed, leading to cortisol synthesis to presumably prevent virilization of female fetuses.[10] In concert with the morphologic changes in the fetal adrenal gland, DHEA, pregnenolone, 17OH-pregnenolone, and their respective sulfated conjugates are secreted. The steroid output amounts to approximately 200 mg/day, of which 60% is DHEAS.[11] As noted above, DHEAS is a major substrate for estrogen biosynthesis via the fetoplacental unit (Fig. 90.2). The fetal adrenal gland provides approximately 60% of the DHEAS for placental estradiol synthesis.[12] Of note, 16α-hydroxyl-DHEAS, metabolized by the fetal liver, provides the substrate for placental estriol synthesis.

Enzymes expressed in the fetal zone include steroidogenic acute regulatory protein (StAR), P450c11A1, P450c17A1, P450c21A2, P450c11B1/B2, and sulfotransferase family 2A member 1 (SULT2A1). Two enzymes, 3β-HSD2 and aldo-keto reductase family 1 member C3 (ARK1C3), are constitutively expressed throughout the first and second trimesters of gestation.[13] The outer definitive/adult zone is largely inactive during the first two trimesters of gestation and begins to produce cortisol during the third trimester.

After 24 to 28 weeks of gestation, the fetal adrenal directly secretes cortisol. Evaluation of second-trimester human adrenals showed the presence of cortisol. Intraadrenal steroid content, measured in second-trimester human fetal adrenal glands, showed that pregnenolone was the most abundant steroid; 17-OHP, progesterone, DHEAS, and cortisol were detectable, whereas aldosterone was undetectable.[14]

Cortisol promotes terminal differentiation of specific tissues such as lung, thyroid, and liver in anticipation of postnatal life.[15] Regarding the lung, cortisol promotes structural maturation of the lung and stimulates fetal lung surfactant synthesis.[16] At birth, the adrenals weigh 8 to 9 g, which is comparable to the weight of adult adrenals. Over the few months following birth, the cells in the fetal zone undergo apoptosis, leading to involution of the fetal adrenal zone.[17] The timing of this involution appears to be more closely tied to gestational age rather than the birth of the infant.[18]

POSTNATAL ADRENAL MORPHOLOGY AND FUNCTION

Postnatally, a precipitous fall in adrenal weight by approximately 50% occurs due to the involution of the fetal zone. The definitive zone persists and develops into the adult adrenal cortex. The adult adrenal cortex is organized into three functionally distinct concentric zones, which were initially described in 1866.[19] The names of the zones reflect the organization of the cells within each region. Cells of the outer zone, the zona glomerulosa, are organized into round clusters (Latin *glomus*, ball). Cells of the middle zone, the zona fasciculata, are arranged in radial pillars or cords (Latin *fascicle*, bundle). Cells of the innermost zone, zona reticularis, form a mesh-like structure (Latin *rete*, net).[20] Lineage-tracing

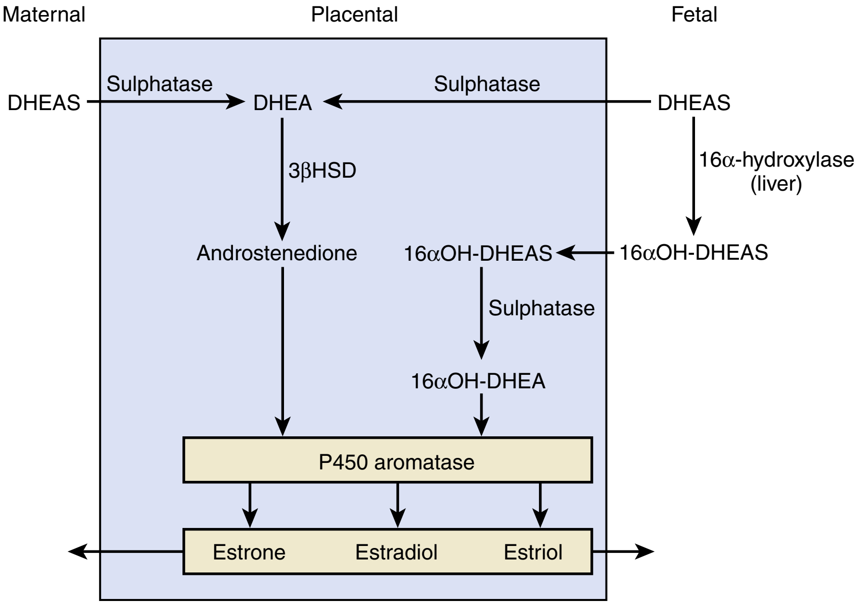

Figure 90.2 **The fetal-placental-maternal steroid unit.** *DHEA*, Dehydroepiandrosterone; *DHEAS*, dehydroepiandrosterone sulfate.

studies have confirmed that adrenocortical cells originate in the outer portion of the cortex and progressively move towards the medulla. These functional status of these cells changes during this process.[21]

The outer zone, the zona glomerulosa, secretes aldosterone. Zona glomerulosa function is regulated by the renin-angiotensin system and serum potassium concentrations. The enzyme aldosterone synthase encoded by the aldosterone synthase (*CYP11B2*) gene is only expressed in the zona glomerulosa.

The zona fasciculata secretes cortisol in response to ACTH acting through the ACTH receptor encoded by the melanocortin-2 receptor (*MC2R*) gene. ACTH has chronic and acute effects. Chronic or tonic ACTH stimulation is essential to promote transcription and translation of adrenal steroidogenic enzymes. ACTH acts acutely to stimulate cortisol secretion. Cortisol induces negative feedback inhibition at the hypothalamus and pituitary. Activity of the hypothalamic–pituitary–adrenal (HPA) axis is organized into circadian and ultradian rhythms, with the highest ACTH and cortisol secretion in the early morning hours prior to awakening.[22] Due to its lipophilic nature, cortisol must be synthesized *de novo* because it cannot be stored in vesicles.

The inner zone, the zona reticularis, secretes DHEA, DHEAS, and androstenedione. Despite being labeled as "adrenal androgens," these C19 steroid hormones do not activate the androgen receptor. Rather, these hormones can be considered to be "prohormones" that can be converted to androgens and estrogens in peripheral tissues. DHEAS, the steroid hormone circulating in the greatest abundance, shows no diurnal variation. The 7- to 10-hour half-life of DHEAS likely contributes to this lack of diurnal variation.[23] Extraadrenal conversion between DHEA and DHEAS through reversible sulfoconjugation by SULTA2 (adrenal and liver) and steroid sulfatase (peripheral tissues) activity. These reversible enzyme activities enable tissue-specific regulation of steroid hormone exposure, also known as intracrinology.[24,25]

The human adrenals are the primary source of the 11-oxygenated metabolites of testosterone and androstenedione, 11β-hydroxyandrostenedione (11OHA4) and 11β-hydroxytestosterone (11OHT). In peripheral tissues, these hormones are converted to 11-ketoandrostenedione (11KA4), 11-ketotestosterone (11KT), and 11-ketodihydrotestosterone (11KDHT). Collectively, these 19-carbon steroids containing an oxygen atom on carbon 11 are referred to as the 11-oxyandrogens (11oAs). The androgenic potencies of 11KT and 11KDHT are comparable to those of testosterone and dihydrotestosterone, respectively.[26-28]

KEY POINTS

- Postnatally, the fetal zone involutes leaving the definitive zone to develop into the three distinct zones of the adult adrenal cortex: the zona glomerulosa, the zona fasciculata, and the zona reticularis, which secrete aldosterone, cortisol, and C19 steroid hormones, respectively.

Clinical Facets of Adrenarche

Adrenarche represents the peripubertal maturation of the adrenal cortex. It has been arbitrarily defined as the rise in adrenal androgens, DHEA, DHEAS, and androstenedione that occurs between 6 and 8 years of age. Despite this commonly used definition, the maturation of the adrenal cortex may truly be a more gradual process; urinary steroid markers of adrenarche show a continuous rise starting at 3 to 4 years of age.[1] This concept is supported by a report regarding a small group of Finnish children in whom DHEAS concentrations were measurable at 1 year of age and correlated with DHEAS concentrations at 6 years of age.[29] Despite much investigation, the factors initiating the onset of adrenarche and subsequently regulating adrenal C19 steroid secretion remain unknown. Studies involving monozygotic and dizygotic twins indicate heritability for onset of adrenarche to be 58% to 61%.[30,31] Although small case-control studies assessed for genetic markers associated with age at adrenarche, no distinct genetic markers were consistently identified and validated.[32,33]

Pubarche is the clinical manifestation of adrenarche. Pubarche is characterized by the development of pubic or axillary hair, adult apocrine odor, acne, and increased oiliness of the skin and hair. In girls, the pubic hair growth typically starts on the labia. Among boys, both adrenal and testicular C19 steroids promote pubic and axillary hair development. The most recent large cross-sectional study, the Third National Health and Nutrition Study conducted between 1988 and 1994, reported mean ages for pubic hair development among American youth. For girls, the mean ages for pubic hair development were 9.5 years for non-Hispanic Blacks, 10.3 years for Mexican Americans, and 10.5 years for non-Hispanic Whites. For boys, mean ages for pubic hair development were 11.1 years for non-Hispanic Blacks, 12.3 years for Mexican Americans, and 12 years for non-Hispanic Whites.[34]

Premature pubarche is arbitrarily defined as occurring when pubic hair growth appears before 8 years of age in girls and before 9 years of age in boys. The most common cause of premature pubarche is premature adrenarche. Because premature adrenarche is a diagnosis of exclusion, other disorders associated with androgen excess need to be excluded. The differential diagnosis includes congenital adrenal hyperplasia, androgen-secreting tumors, cortisone reductase deficiency, apparent cortisone reductase deficiency, 3'-phospho-adenosine 5'-phosphosulfate synthase deficiency, glucocorticoid resistance, Cushing syndrome, and exposure to exogenous androgens (Table 90.1).

Premature adrenarche is more common in girls than in boys.[35] Children with premature adrenarche tend to be taller. Skeletal maturation is normal or minimally advanced. Skeletal maturation is assessed by an x-ray of the left hand and wrist to evaluate the ossification centers.[36] When the skeletal maturation is significantly advanced, greater than two standard deviations (SDs), concerns arise regarding the potential for adult short stature. Despite conflicting outcome studies, most children achieve an adult height appropriate for their predicted midparental height.[37-40] The mini growth spurt in normal children that also occurs at around 6 to 8 years of age is probably not a function of adrenarche.[41] Importantly, the finding of a significantly advanced bone age (>2 SDs) in a child with premature adrenarche should prompt evaluation for other disorders associated with premature pubarche, such as nonclassic congenital adrenal hyperplasia and androgen-secreting tumors.[42] Because all children have an increase in adrenal androgen production between 6 and 8 years of age, why hair development occurs in a small minority of children remains puzzling. In addition to DHEA, DHEAS, and androstenedione, the 11-oxygenated C19 steroid adrenal androgens play a role in the clinical signs of adrenarche.

TABLE 90.1 Differential Diagnosis of Premature Pubarche

Premature adrenarche
Congenital adrenal hyperplasia
Androgen-secreting tumor (adrenal, ovary, or testis)
Human chorionic gonadotropin-secreting tumor
Apparent cortisone reductase deficiency
Cortisone reductase deficiency
Apparent dehydroepiandrosterone sulfate sulfotransferase deficiency
Cushing syndrome
Familial glucocorticoid resistance
Exposure to exogenous androgens

KEY POINTS

- The factors governing onset of adrenarche remain unclear.
- The diagnosis of premature adrenarche can be made by the presence of pubic hair before the age of 8 years in girls and 9 years in boys.
- Premature adrenarche should be differentiated from more serious conditions such as congenital adrenal hyperplasia and virilizing tumors.

Associations reported between low birth weight and premature adrenarche have been inconsistent.[43] Sexual dimorphism is not apparent in normal children, in whom a relationship between lower birth weight and higher adrenal androgen levels is present in both sexes.[44] Androgens and estrogens affect skeletal maturation and bone health through their actions on osteoblast, osteocytes, and osteoclasts.[45] In a small study of girls with premature adrenarche, increased linear growth was already evident in the first 2 years of life and associated with higher IGF-1 levels.[46] Obesity can further accelerate the rate of skeletal maturation in premature adrenarche.

Levels of 11oAs have been measured in several disorders, including castration-resistant prostate cancer,[47] 21-hydroxylase deficiency,[48-50] and polycystic ovarian syndrome (PCOS).[26,51] A recent study showed that 11oAs correlate with surrogate markers of metabolic risk in a large cohort of women with PCOS.[51] The 11oAs also appear to significantly contribute to the clinical signs observed in adrenarche,[26,27,47] including premature adrenarche.[52] Recent findings suggest that elevated 11oAs—rather than DHEA, DHEAS, and A4—may be of particular diagnostic and clinical significance in cases of clinical signs of adrenarche (premature pubarche) without the biochemical diagnosis of premature adrenarche based on DHEAS levels (for premature adrenarche definition, see "Clinical Facets of Adrenarche" later).[53] Wise-Oringer et al. have proposed that measurement of serum 11oAs may be a more accurate way to screen and classify children with premature adrenarche than measurement of serum DHEAS.[53] These findings could potentially also be broadly applied to other disease states of androgen excess.

Obesity, hyperinsulinemia, and/or insulin resistance have been observed in children with premature adrenarche, and the molecular basis of these findings is likely multifactorial. Obesity exacerbates insulin resistance and hyperinsulinemia, which can promote increased adrenal and gonadal steroid secretion. Adiposity may influence the association between elevated adrenal androgens and signs of metabolic syndrome. Children evaluated for premature adrenarche should be clinically followed for signs of metabolic syndrome, although these relationships remain to be fully elucidated.[54-59] These studies report associations without establishing causality.

The question regarding the risk for girls with premature adrenarche to develop PCOS in later life was initially based on findings in a cohort of Catalan girls. Of these girls who had been previously diagnosed with premature pubarche, 45% developed functional ovarian hyperandrogenism.[60] Additional features of dyslipidemia, increased visceral fat, hyperinsulinemia, inflammatory marker changes, and early menarche were also identified in this cohort.[61] Daughters of mothers with PCOS are at higher risk for developing this syndrome, and a significant number exhibit exaggerated adrenarche.[62] Studies investigating the relationship between premature adrenarche and PCOS have led to a proposed developmental sequence beginning with reduced fetal growth, followed by a postnatal catch-up in height and weight, premature adrenarche, and finally clinical androgen excess and PCOS, with hyperinsulinemia and increased hepatovisceral fat stores playing a key role.[63-66]

Still, among retrospective studies, the development of PCOS in girls with premature adrenarche varies.[67-69] Not all girls with premature adrenarche develop PCOS, and conversely, not all girls with PCOS have a history of premature adrenarche.[70] Inquiry into the relationship of premature adrenarche to PCOS can be a challenge, because the diagnostic criteria for PCOS include normal features for peripubertal development during adolescence, such as irregular menses, polycystic ovary morphology, and mild hyperandrogenism.[71] Anti-Müllerian hormone (AMH) concentrations are typically elevated in women with PCOS, and AMH has been assessed as a possible tool to predict PCOS in girls with premature adrenarche. Whereas one study reported that AMH concentrations were significantly higher in girls with premature adrenarche and correlated with maternal history of PCOS,[72] another study suggests that AMH may not have adequate predictive value for the diagnosis of PCOS.[73] Currently, AMH should not be used to predict and diagnose PCOS.

Currently, no blinded randomized controlled trials exist to provide evidence-based data regarding the use of insulin sensitizers in a child presenting with typical clinical and biochemical features of premature adrenarche. It is appropriate to counsel parents that some girls with premature adrenarche may later experience menstrual disturbances in adolescence. Early intervention after menarche with insulin sensitizers may prevent progression to PCOS and reduce the risk for long-term cardiovascular problems.[74] Counseling regarding healthy lifestyle choices is also important.

KEY POINTS

- Associations between premature adrenarche and bone age advancement, obesity, hyperinsulinemia, insulin resistance, and polycystic ovary syndrome have been described.

Adrenal Steroidogenesis

The initial step in steroidogenesis is the conversion of cholesterol to pregnenolone. The P450c17 enzyme functions as the qualitative regulator of steroidogenesis.[75] This enzyme uniquely catalyzes both 17α-hydroxylase and 17,20-lyase activities. It is the latter enzyme activity that preferentially ensures C19 steroid production and, in particular, DHEA synthesis and adrenarche. A number of factors enhance the differential activities of P450c17. These include posttranslational regulation of P450c17 by phosphorylation on serine/threonine residues and the role of electron transfer proteins.[76-78] The principal electron donor to microsomal P450 enzymes, including P450c17, is nicotinamide adenine dinucleotide phosphate cytochrome P450 oxidoreductase. This enzyme cofactor augments both 17α-hydroxylase and 17,20-lyase activities but is not the principal determinant of increased DHEA synthesis. Enhancement of 17,20-lyase activity is linked specifically to the action of cytochrome b_5 in the presence of adequate P450 oxidoreductase.[75] This effect is far more substantial with Δ^5 substrates such as 17OH-pregnenolone as compared with a Δ^4 substrate such as 17OH-progesterone, hence the predominance of DHEA synthesis. Coupled to the promotion of DHEA synthesis is a relative deficiency of 3β-hydroxysteroid dehydrogenase (HSDB2) in the fetal adrenal and postnatal zona reticularis. This enzyme would normally compete with P450c17 to convert Δ^5 to Δ^4 steroids.[79]

Mutations in the gene encoding P450 oxidoreductase lead to a biochemical profile reminiscent of combined partial 17α-hydroxylase and 21-hydroxylase deficiencies with virilization in affected girls and undervirilization in affected boys.[80,81] Antley–Bixler syndrome, a condition characterized by severe skeletal abnormalities, genital anomalies, and adrenal dysfunction, is also a manifestation of this enzyme deficiency.[82]

More than 99% of DHEA is sulfated to DHEAS through the action of dehydroepiandrosterone sulfatase (SULT2A1).[83] Sulfated steroids are unavailable as substrates for HSDB2 activity, thus maintaining the high levels of DHEAS. Immunohistochemical

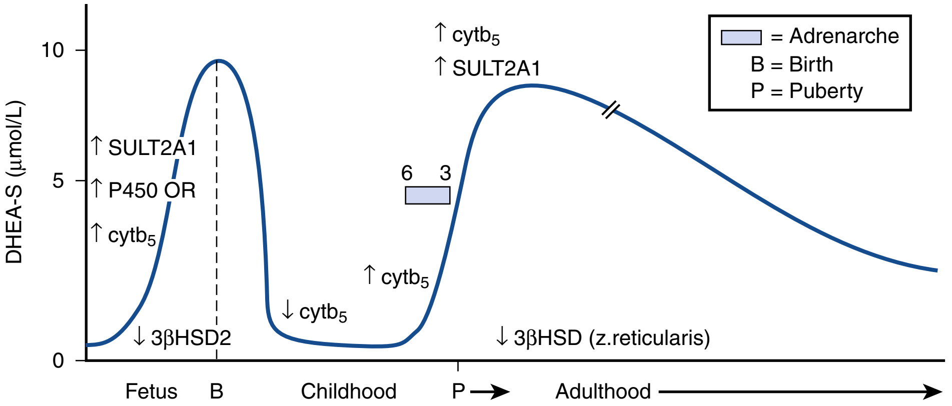

Figure 90.3 Schematic of dehydroepiandrosterone sulfate (DHEAS) production from fetal to adult life. The *arrows* indicate temporal changes in factors controlling DHEAS.

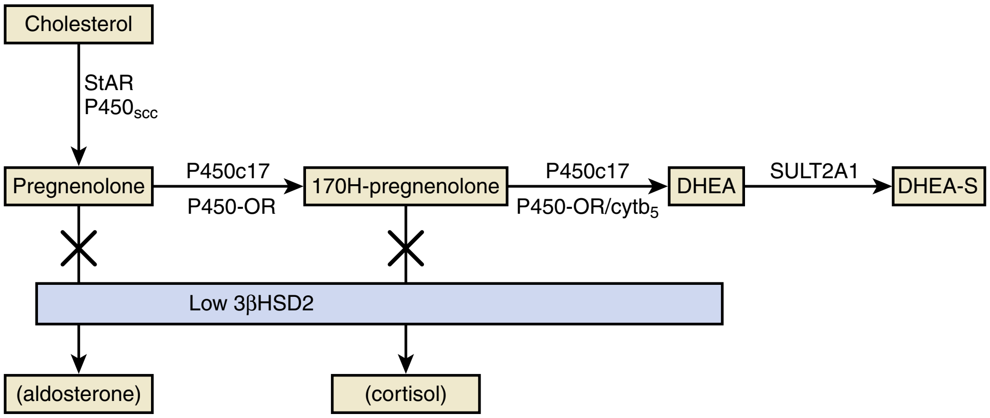

Figure 90.4 Pathway of dehydroepiandrosterone sulfate (DHEAS) synthesis in fetal adrenal and adult zona reticularis. Also depicted is the effect of low expression of 3β-hydroxysteroid dehydrogenase 2 (3β-HSD2) in these tissues.

studies in the fetal adrenal gland and in age-related postnatal adrenal glands have demonstrated a developmental pattern of enzyme and cofactor expression that may explain the intraadrenal control of adrenarche.[84-86] In summary, the pattern of increased DHEAS secretion is associated with increased expression of P450c17, P450 oxidoreductase, cytochrome b_5, SULT2A1, and decreased expression of HSDB2 in the fetal adrenal gland and again in the postnatal zona reticularis after 5 years of age. In contrast, a reversal of this pattern occurs in the postnatal adrenal gland between infancy and 5 years of age. Expression of cytochrome b_5 and SULT2A1 is maintained beyond the adult age, when DHEAS levels start to decline. The zona reticularis becomes smaller with increasing age, suggesting that the decline in DHEAS levels is associated with a decrease in cell number rather than a change in enzyme content. What factors stimulate the changes in expression of key proteins controlling DHEAS synthesis remain to be determined. HSDB2 has the important function of determining the ratio of Δ^5 and Δ^4 steroid production. A family of orphan nuclear receptors (nerve growth factor-induced clone B) is expressed in parallel with HSDB2 and directly acts on the promoter to upregulate the *HSD3B2* gene (Figs. 90.3 and 90.4).[87]

DEHYDROEPIANDROSTERONE AND *IN VITRO* FERTILIZATION

DHEA has been used as a supplemental treatment for women undergoing *in vitro* fertilization, particularly in patients who respond poorly to gonadotropin stimulation. Regarding the definition of poor ovarian response (POR), The European Society of Human Reproduction and Embryology has recommended that at least two of the following three criteria should be present in identifying a patient as a potential poor responder to ovarian stimulation: (i) advanced maternal age or any other risk factor for POR; (ii) a previous POR; and (iii) an abnormal ovarian reserve test.[88] However, defining POR is still unclear, as randomized trials on POR have often used differing definitions.[89]

The use of DHEA supplementation for POR was first suggested in 2000 in a case series.[90] A worldwide survey found that 25.8% of *in vitro* fertilization (IVF) clinicians in 45 different countries use DHEA to supplement IVF treatment protocols in women with POR.[91] Studies have shown that DHEA treatment may increase the number of oocytes, increase embryo numbers and quality, increase pregnancy rate, increase live birth rate, and decrease miscarriage rate.[92-96] In a systematic review and metaanalysis of six randomized controlled trials (RCTs) of DHEA supplementation in women undergoing IVF (five studies in women with POR, one in women without POR), the pooled estimates suggested that DHEA supplementation was associated with a significant increase in clinical pregnancy, endometrial thickness, and retrieved oocytes. No relationship was identified to an improvement in live birth rate, embryos transferred, or an increase of estradiol on human chorionic gonadotropin day.[97] Additionally, several studies have found no significant differences in the parameters mentioned; one RCT, for example, failed to show that DHEA supplementation significantly improved IVF outcomes.[98] Another study found that, in women undergoing DHEA supplementation, the markers of very early (AMH) and early differentiated (inhibin B) follicles were not different compared with controls, whereas antral follicle count increased significantly, suggesting that DHEA specifically targets the 2- to 10-mm antral cohort of follicles that have escaped atresia for that particular cycle, improving follicular survival.[99]

The presumed major mechanism of DHEA in improving reproductive outcomes is the increase in androgen levels, because DHEA serves as a precursor to estrogen and testosterone. Androgen receptors are expressed in the granulosa cells, theca cells, and oocytes as follicles mature.[100] In this situation, DHEA may act through intracrine mechanisms, allowing for tissue-specific modifications compared with androgens such as testosterone. This may explain the more precise actions and fewer adverse effects of DHEA supplementation compared with testosterone supplementation.[24] Studies have suggested that DHEA could have mitochondrial effects, increasing mitochondrial mass, reducing mitochondrial apoptosis, and restoring mitochondrial homeostasis in cumulus cells and granulosa cells.[101,102] The exact mechanism of DHEA supplementation in augmenting IVF in poor responders is therefore likely multifaceted and remains to be fully understood.[103] More studies, particularly randomized controlled trials, are needed to establish a clearer picture of the mechanisms of DHEA on improving reproductive outcomes in women undergoing IVF and the efficacy and safety of this intervention.

KEY POINTS

- Dehydroepiandrosterone has been used as supplementation for women undergoing *in vitro* fertilization, possibly working through intracrine mechanisms as a precursor to estrogen and testosterone. More randomized controlled trials are needed to determine the efficacy and safety of this intervention.

Adrenopause

The term “adrenopause” refers the observation that DHEA and DHEAS concentrations decline following peak DHEA and DHEAS during the mid-20s. DHEA and DHEAS concentrations at 80 years of age are only 20% of those at age 25 years.[104] Despite decreasing DHEA and DHEAS concentrations, glucocorticoid and mineralocorticoid secretion are largely unchanged. In a longitudinal study of women (Study of Women’s Health Across the Nation), a modest perimenopausal increase was noted in DHEAS concentrations; this was accompanied by stable testosterone concentrations and minimal decreases in androstenedione concentrations.[105] During the perimenopausal period, DHEAS concentrations were lower in Black women than in White women.[106]

In a study involving 100 premenopausal and 100 postmenopausal women, sulfated steroids, i.e., DHEAS, 17-hydroxypregnenolone, and androstenediol-3-sulfate, showed a negative correlation with age.[107] Yet, despite the decline in DHEA and DHEAS concentrations, the 11oAs did not decline among aging women. Among these women, no significant associations between steroid concentrations, body mass index (BMI), hypertension, dyslipidemia, hyperglycemia, or bone density were identified. With expansion of this dataset to include more women and men, 11OHA4 and 11OHT concentrations were noted to slightly increase in women while remaining stable in men across adult ages. In this population, 11KT concentrations showed positive correlation with 11KA4, 11OHT, and 11OHA4 in both sexes.[108] After adjusting for age, androstenedione concentrations declined and were inversely related to BMI in both sexes. Of the 11oAs, 11OHT increased with BMI in women, whereas 11KT increased with higher BMI in men.[108] As would be anticipated, testosterone concentrations were higher in men compared with women; 11OHA4, 11KA4, and 11KT concentrations were minimally higher among men.[108] The factors responsible for the decreased DHEA/DHEAS production and the dissociation of DHEA/DHEAS production from the 11-oxygenated C19 steroids are indeterminate.

This decline in DHEA and DHEAS concentrations is accompanied by immunohistochemical changes in the adrenal cortex of older adults. Specifically, using human adrenal tissues obtained from reproductive-aged adults and older adults, expression of both CYB5A2 and SULT2A1 in the adrenal glands from older individuals was reduced. Similar to the findings in adrenal glands obtained from older women, adrenals from older men demonstrated a less distinct zona fasciculata/zona reticularis zonation and more commonly displayed areas where cells expressing HSD3B2 and CYB5A intermingled.[108] The molecular basis for these changes in zona reticularis function is unknown. The small sample size, cross-sectional nature, and incomplete clinical information limit conclusions from these studies.

KEY POINTS

- Adrenopause refers to the fall in adrenal production of dehydroepiandrosterone and dehydroepiandrosterone sulfate that occurs in later life.

Epidemiology/Associations with Dehydroepiandrosterone Sulfate Concentrations, Aging, and Cardiovascular Risks

Cross-sectional epidemiologic studies have queried the relationship between declining DHEAS concentrations and various aspects of aging. A 1986 study showed DHEAS concentrations to be inversely related to death from any cause and to death from cardiovascular disease in men over 50 years of age.[109] These findings were not replicated in adult women in the Rancho Bernando Study.[110] The Osteoporotic Fractures in Men study in Sweden was a 5-year longitudinal study that involved 2416 men between 69 to 81 years of age; this study reported that low DHEA and DHEAS concentrations predicted an increased risk for coronary heart disease but not cerebrovascular disease.[111] Results from the Women’s Ischemia Syndrome Evaluation reported a greater than 2-fold increased risk of cardiovascular disease mortality among women in the lowest tertile of DHEAS compared to those in higher categories (hazard ratio = 2.55; 95% confidence interval: 1.19–5.45).[112] A metaanalysis involving 18 studies with a total of 92,489 patients concluded that the prognosis was poorer for patients with cardiovascular disease and lower DHEAS levels compared with those with higher DHEAS concentrations.[113] Hence, current data suggest that lower DHEAS concentrations are associated with an increased risk for cardiovascular disease.

The Atherosclerosis Risk in Communities (ARIC) study assessed some features of the cardiovascular disease. In the ARIC study, lower DHEAS concentrations were associated with increased risk for subclinical myocardial injury, heart failure hospitalization, and death in men and women.[114] White participants tended to have lower DHEAS concentrations compared with Black participants. Within this cohort, men who experienced a greater decline in DHEAS concentrations showed an increased risk for hospitalization for heart failure. Their data suggest a threshold effect in which low DHEAS concentrations are associated with increased risk, but higher concentrations do not modify the risk for heart failure and death.

Among postmenopausal women, DHEAS concentrations were weakly but significantly related to endothelial function independent of other coronary risk factors, suggesting a protective effect of DHEA on the endothelium with improved endothelial cell function.[115] To elucidate the basis for the association of low DHEAS concentrations with myocardial injury, Jia and colleagues utilized a proteomics assay and Ingenuity Pathway Analysis. Significant associations between DHEAS concentrations and proteins with known functions pathways involved in the extracellular matrix and cardiac remodeling were identified. The association of DHEAS concentrations with POMC and Agouti-related protein, which are melanocortin receptor agonists and antagonists, respectively, suggests that DHEAS concentrations may indicate HPA axis dysfunction in older adults.[114] Low DHEAS concentrations appear to predict risk for heart failure in older adults.[114] However, whether DHEAS has a direct, indirect, or passive bystander role in myocardial remodeling remains to be determined.

DHEAS concentrations appear to be associated with risk for ischemic strokes. In the Nurses' Health Study, lower DHEAS concentrations were associated with increased risk for ischemic strokes.[116] Potential mechanisms for DHEAS actions could include inhibiting migration and proliferation of cells within the vascular wall, thereby increasing vascular smooth muscle apoptosis and decreasing vascular remodeling following injury.[117] In addition, animal models suggest that DHEAS may influence insulin resistance by affecting hepatocyte glucose production and improving peripheral tissue glucose clearance.[118,119] Nevertheless, the question as to whether DHEAS plays an active role in the metabolic pathways or is merely a marker remains to be answered.

KEY POINTS

- Adrenopause is accompanied by immunohistochemical changes in the adrenal cortex but is not accompanied by changes in glucocorticoid, mineralocorticoid, or 11-oxyandrogen production.
- Declining dehydroepiandrosterone sulfate concentrations may be associated with various aspects of aging, including increased risk for cardiovascular disease and ischemic strokes.

NEUROBIOLOGY OF DEHYDROEPIANDROSTERONE AND DEHYDROEPIANDROSTERONE SULFATE

DHEA and DHEAS concentrations are higher in the brain than in peripheral circulation.[120] One likely explanation for this finding is that both DHEA and DHEAS are synthesized *de novo* in the brain in astrocytes and neurons. For this reason, DHEA and DHEAS are considered to be "neurosteroids." Another source of brain DHEA is peripheral DHEA, which can readily cross blood–brain barrier due to its lipophilic nature. In contrast, brain DHEAS is more likely synthesized in the brain because its hydrophilic nature interferes with crossing the blood–brain barrier.[121]

Several mechanisms are likely responsible for DHEA/DHEAS actions. The most obvious mechanism is conversion of DHEA/DHEAS to more potent sex steroids, followed by activation of androgen or estrogen receptors in specific target tissues.[24] In addition, DHEA/DHEAS can bind to the tropomyosin-related kinase (TrkA), γ-aminobutyric acid type A ($GABA_A$), sigma subtype 1, and NMDA receptors.[122] DHEA/DHEAS appear to have inhibitory actions at the $GABA_A$ receptor, whereas they act as agonists at the sigma 1 receptor.[123] DHEA has been described as a modulator of neurotransmission because it can affect serotonin, γ-amino butyric acid (GABA), glutamate, and dopamine levels. In the central nervous system, it can be metabolized to ADIOL, which can bind to ERβ, negatively regulating proinflammatory gene expression.[124]

Neurobiological actions of DHEA/DHEAS include neuroprotection, neurite growth, neurogenesis, and neuronal survival. At low nanomolar concentrations, in primary cultures of mouse embryonic neocortical neurons, DHEA promoted growth of Tau-immunopositive axons; in contrast, DHEAS had no effect on axonal growth and stimulated dendritic growth.[123] In human fetal cortical neural stem cells, DHEA promoted neurogenesis and neuronal survival; this effect was blocked by an NMDA receptor antagonist and sigma 1 receptor antagonists.[125] In addition, DHEA has antiglucocorticoid and neuroprotective effects. Animal studies, both *in vivo* and *in vitro*, have demonstrated that DHEA protects against the neurotoxic effects of corticosterone.[126] Neurotrophins and their tyrosine kinase receptors influence neuronal differentiation, growth, and survival. DHEA binds to TrkA and TrkC receptors and induces receptor phosphorylation. The functional significance of this finding in human biology is unclear.[127] In a mouse model involving lipopolysaccharide stimulation, DHEA appeared to act as an endogenous regulator of neuroinflammatory microglial responses. The proposed mechanism involves interactions with the tropomyosin-related kinase receptor (TrkA), which activated the Akt1/Akts2-CREB pathway, ultimately resulting in enhanced expression of the histone 3 lysine 27 (H3K27) demethylase Jumonji d3 (Jmjd3).[128]

Preclinical findings have led to clinical investigations assessing DHEA/DHEAS concentrations and potential for therapeutic interventions. For example, researchers in traumatic stress have been intrigued by the potential relationship between post-traumatic stress disorder (PTSD) and DHEA/DHEAS. Elevated DHEA and low cortisol/DHEA or low cortisol/DHEAS concentrations have been described in some studies. A metaanalysis reviewing a modest number of publications found no consistent relationship between PTSD and DHEA/DHEAS concentrations. The heterogeneity of the results and use of only a single hormone determination without regard to time of day/diurnal rhythm confound interpretation of these studies. Nevertheless, there appeared to be an association between increased basal DHEA/DHEAS concentrations with a trauma exposure irrespective of PTSD development.[129]

Measuring hormone samples is hair samples provides a mechanism to circumvent the methodological issues associated with using a single hormone determination to characterize a dynamic hormone. In a study involving self-reports on psychopathology and coping in 92 Palestinian girls aged 11 to 16 years affected by the Israeli–Palestinian conflict, trauma-exposed girls had significantly higher DHEA and lower cortisol/DHEA ratios in their hair than non-trauma-exposed girls.[130]

DHEA has been found to have effect on immune and endothelial function. Available data are accumulating indicating that the cortisol-to-DHEAS ratio may be a useful indicator of chronic stress in humans. Indeed, this ratio may provide an indicator of chronic stress in non-human animal species and may be useful for animal welfare studies.[131]

In animal models for multiple sclerosis, DHEA and DHEAS may be beneficial. DHEA suppresses Th17 cell responses, reduces microglia-mediated neuroinflammation, and expands IL-10-producing regulatory T-cell populations in an ERβ-dependent manner. DHEAS decreases demyelination and axonal loss.[124]

KEY POINTS

- Dehydroepiandrosterone (DHEA) and dehydroepiandrosterone sulfate (DHEAS) are synthesized *de novo* in the brain, and their actions are regulated by several mechanisms.
- DHEA/DHEAS can contribute to neuroprotection, neurite growth, neurogenesis, and neuron survival and have been shown to be increased in traumatic stress.

Clinical Implications of Dehydroepiandrosterone Sulfate/Dehydroepiandrosterone

Data were obtained in the English Longitudinal Study of Aging using a community-based population to assess for an association between DHEAS concentrations and depression; data were obtained at baseline and at 4 years. Although no associations were apparent between DHEAS concentrations and depression at baseline, low DHEAS concentrations obtained at baseline predicted future depressive symptoms independent of age, gender, economic circumstances, and health behaviors and characteristics.[132] DHEAS concentrations fall after acute injury/trauma. Whereas cortisol concentrations typically increase during septic shock, DHEAS concentrations fall.[133] Among patients with schizophrenia, increased serum DHEA and lower cortisol/DHEA ratios were reported and associated with an inverse relationship between hippocampal volume and cortisol/DHEA ratio.[134]

Dehydroepiandrosterone Sulfate/Dehydroepiandrosterone and "The Fountain of Youth"

The observation that DHEA/DHEAS concentrations declined concomitant with onset of aging led to the hypothesis that provision of supplemental DHEA/DHEAS could restore physical health and protect the brain from the degenerative changes due to age. This hypothesis was supported by association studies linking decreased DHEA and DHEAS concentrations to decreased bone mineral density, increased risk of fracture, decrease cognitive function, decreased quality of life, and increased risk of cardiovascular disease.[135] Based on this hypothesis, DHEA/DHEAS replacement therapy was tried in older adults.

In the study by Nair et al., administering DHEA for 2 years had no effect on body composition, physical performance, or insulin sensitivity.[136] No effects were observed on insulin secretion, insulin action, and suppression of systemic lipolysis following mixed meal or glucose tolerance tests.[137,138] Most clinical studies of DHEAS administration in Alzheimer disease enrolled more females than males; no improvement in cognition was seen with DHEAS treatment.[139]

No consistent data supporting a benefit of DHEA supplementation on body composition, cognition, mood, or sexual function in older men.[140] RCTs of DHEA supplementation have yielded inconsistent results regarding clinical benefits. Improved arterial elasticity was observed among a heterogeneous group of elderly men and women treated with DHEA (50 mg/day) for 1 year.[141] One potential clinical indication for DHEA treatment is vaginal dryness; daily intravaginal 0.05% DHEA improved vaginal dryness and decreased dyspareunia.[142]

Hence, no evidence-based data exist substantiating that DHEA and DHEAS are the proverbial "fountain of youth."[143] However, the US Food and Drug Administration classifies these steroids as dietary supplements rather than drugs (DHEA Uses, Benefits, and Side Effects; verywellhealth.com). This means that distribution of these medications is unregulated and does not require a prescription. Hence, DHEA is available for personal use; these preparations have been found characterized to contain 0–150% of the amount stated on the package.[144]

KEY POINTS

- There is limited evidence that supplemental dehydroepiandrosterone can improve quality of life.

CONCLUSION

Despite being the most abundant circulating hormones in the circulation, the precise physiologic actions of DHEA and DHEAS remain mysteries. DHEA and DHEAS are secreted by the adrenal cortex and synthesized *de novo* in the brain. These hormones play a major role as substrates for placental estrogen synthesis in the fetus. DHEAS production escalates at adrenarche, peaking in early adulthood. Yet, the factors influencing adrenocortical DHEA/DHEAS secretion remain indeterminate. Low DHEAS concentrations appear to be associated with an increased risk for cardiovascular disease in older adults. Investigation into DHEA/DHEAS actions are uncovering effects on endothelial cells, immune function, and neuronal development. Much, however, remains to be elucidated regarding the physiologic roles and regulation of DHEA and DHEAS.

ANATOMIC PATHOLOGY IN DEVELOPMENTAL ABNORMALITIES OF THE ADRENAL GLAND

The adrenal cortex consists of steroidogenic cells that originate from the intermediate mesoderm.[1] A web of factors, including transcriptional factors (e.g., DAX1 encoded by *NR0B1*, SF1/Ad4BP encoded by *NR5A1,* and GATA4/6 encoded by *GATA4* and *GATA6*), play a crucial role during the organogenesis and functional differentiation of adrenocortical cells.[1,2,3] This complex developmental process stems from the formation of adrenogonadal primordia within the urogenital ridge and is followed by the separation of surrounding mesenchyme and formation of an encapsulated adrenal anlagen (fetal adrenal zone), which later develops into the adult adrenal cortex via the expansion and maturation of the definitive adrenocortical zones.[1]

The adrenal medulla consists of chromaffin cells that are surrounded by mesodermal steroidogenic cortical cells. Recent evidence suggests that only a small fraction of the adrenal medulla originates directly from the migratory neural crest cells, whereas preganglionic nerve fiber–related pluripotent Schwann cell precursors at the adrenal anlage provide the major path for the development of chromaffin cells.[4,5]

Disruption in various steps of the organogenesis results in developmental abnormalities. This section provides a brief summary of developmental conditions related to anatomic pathology.

Adrenal Aplasia or Hypoplasia

Adrenal aplasia (agenesis) is a very rare condition that refers to the absence of the adrenal gland, whereas adrenal hypoplasia refers to adrenocortical atrophy. Anencephaly is a well-known cause of neonatal adrenal hypoplasia or aplasia.[6] In humans, *NR5A1* mutations are rare, but they have been reported in bilateral adrenal aplasia or hypoplasia.[2,7] Patients with Pollister–Hall syndrome harbor *GLI3* mutations and can exhibit adrenal hypoplasia.[2] Morphologically, hypoplastic adrenal glands appear to have a prominent medulla due to significantly reduced thickness of the cortex without normal cortical zonation. Several etiologies can result in adrenal hypoplasia (e.g., exogenous glucocorticoid administration, insufficiency related to the hypothalamic-pituitary-adrenal axis, including but not limited to adrenocorticotropic hormone [ACTH] resistance and familial glucocorticoid deficiency syndromes). Congenital adrenal hypoplasia is also linked to *NR0B1*-related pathogenesis. The latter can either manifest with hemizygous pathogenic *NR0B1* variants that cause X-linked adrenal hypoplasia congenita with hypogonadotropic hypogonadism or Xp21 deletion, which results in deletion of *NR0B1* and *GK* (complex glycerol kinase deficiency), and sometimes *DMD* (Duchenne muscular dystrophy).[8] Cytomegalic cells with lipid depletion pattern have been reported in hypoplastic adrenal glands.

KEY POINTS

- Defects in primary and secondary developmental regulators of the adrenal cortex can lead to congenital adrenal aplasia or hypoplasia.

Accessory or Heterotopic Adrenal Tissue

Accessory or heterotopic adrenocortical tissue is not an uncommon finding. These consist of isolated adrenocortical tissue rests and may have associated adrenal medullary cells (chromaffin cells), as seen in an orthotopic adrenal gland. The occurrence of chromaffin cells in heterotopic adrenal tissue also underscores the crosstalk between adrenal cortex and medulla during embryogenesis. Delamination in the adrenogonadal primordia leads to the separation and differential migration of embryonic cells towards the gonadal anlagen and the adrenal anlagen. Therefore, failure in encapsulation of steroidogenic factor 1 (SF1)-expressing developmental cells that are responsible for the formation of the fetal adrenal zone may explain the origin of adrenocortical tissue rests that are identified in the abdomen (e.g., along the celiac axis, kidney and kidney capsule, periadrenal, spleen and splenic hilum, mesentery), as well as in various anatomic locations that are aligned with the developmental tract of the gonads (e.g., spermatic cord, scrotum, broad ligament, uterus, ovarian and spermatic vessels, gonads).[9,10] However, the occurrence of adrenocortical rests in unusual locations such as brain, pituitary, spinal nerves, lung, liver, and pancreas also expands the spectrum of adrenocortical tissue rests that cannot be explained from an embryological point of view.[9,10,11] The term "adrenocortical choristoma" is applied to unusual heterotopic adrenocortical rests (e.g., adrenocortical choristoma in a silent corticotroph tumor).[11] Failure to recognize these atypical locations may lead to diagnostic dilemmas.

Mechanisms that alter with the successful separation of the developmental periadrenal mesenchyme may result in adrenal fusions (union) or adhesions.

Adrenal fusions (unions) occur between the adrenal gland and parenchymal elements of the liver or kidney (e.g., adrenohepatic fusion, adrenorenal fusion) (Fig. 91.1). Morphologically, in the setting of an adrenal fusion, there is no intervening connective tissue capsule separating cellular elements of the organ that is united with the adrenal gland. Therefore, adrenocortical elements are intermingled with cellular components of the other organ. Midline adrenal fusions also occur between both adrenal glands. The latter leads to the gross appearance of a single horseshoe-shaped midline adrenal gland. Other developmental defects, including those of central nervous system, can be identified in patients with midline adrenal unions.[9]

In adrenal adhesions, there is an intact intervening connective tissue capsule separating parenchymal elements of the adrenal gland and the other organ (e.g., adrenohepatic adhesion). As a consequence, the adrenal gland displays a normal medulla and preserved cortical zonation. Failure to recognize the spectrum of developmental abnormalities such as adrenohepatic fusion or adrenohepatic adhesion, and adrenocortical rests in the liver can result in misinterpretation of a benign developmental process as invasion or metastasis of an adrenocortical carcinoma. The latter may be diagnostically challenging, especially in small biopsy specimens.

TUMOR-LIKE LESIONS OF THE ADRENAL GLAND

KEY POINTS

- Tumor-like lesions of the adrenal gland encompass a large spectrum of lesions, including adrenal myelolipoma, ectopic thyroid tissue, ovarian thecal metaplasia, amyloid deposition, adrenal hematoma and hemorrhage, adrenal calcification, adrenal cysts, infection with or without abscess, congenital adrenal hyperplasia, and adrenal cytomegaly with or without Beckwith–Wiedemann syndrome.

Adrenal Myelolipoma

Myelolipoma consists of a mature adipose tissue admixed with variable number of hematopoietic cells, including megakaryocytes (Fig. 91.2). Myelolipomas with extensive hemorrhage can simulate an adrenal hematoma or malignant process. Microscopic foci of myelolipomatous change can occur in adrenocortical proliferations. Bilateral adrenal gland involvement was recorded in association with congenital adrenal hyperplasia (CAH) and primary bilateral macronodular adrenocortical disease (also known as primary bilateral macronodular adrenocortical hyperplasia).[12,13] Giant adrenal myelolipomas exceeding 30 cm have been defined in patients with CAH.[12] Increased ACTH- and androgen-mediated stimulus and overexpression of melanocortin 2 receptor and androgen receptor have been postulated in the developmental pathogenesis of some adrenal myelolipomas, especially in the setting of CAH.[14]

Ectopic Thyroid Tissue

The presence of thyroid tissue within the adrenal gland expands the unusual spectrum of ectopic thyroid tissue outside the usual migratory path of the thyroid anlage that typically lies between the foramen cecum and mediastinum.[15,16] An abnormal descent of the thyroid anlage can be the source of ectopic thyroid tissue that can be identified in adrenals (Fig. 91.3). While diagnosticians are still required to exclude the possibility of metastatic differentiated thyroid carcinoma in any unusual location, failure to recognize the occurrence of ectopic thyroid tissue in abdominal organs may result in misdiagnosis.[15]

Ovarian Thecal Metaplasia

Ovarian thecal metaplasia is a relatively rare tumor-like lesion of the adrenal gland. Originally described in postmenopausal women with markedly elevated gonadotropins, these abnormal cellular nests were defined as wedge-shaped cortical lesions that are composed of ovarian stroma-like elements. However, these lesions have been defined in both women and men. Subsequent evidence also suggested that these

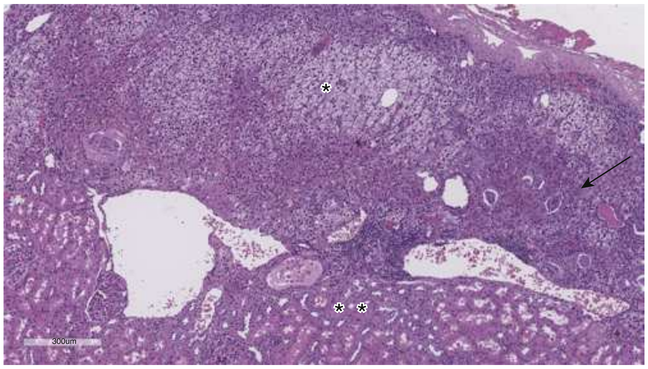

Fig. 91.1 Adrenorenal fusion. The adrenal cortex (*) is in continuity with the renal parenchyma (**). There is no limiting connective tissue between adrenal gland and kidney. The arrow illustrates renal elements in the zona reticularis.

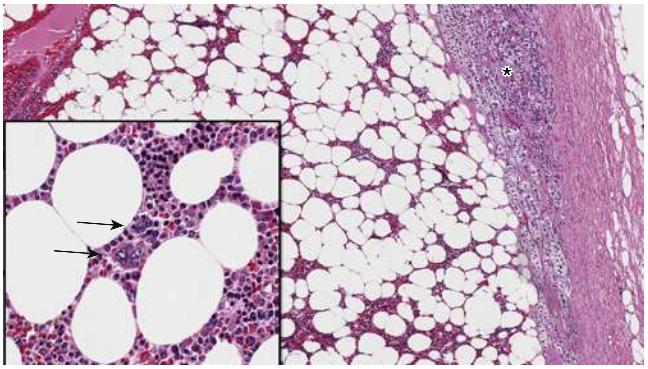

Fig. 91.2 Adrenal myelolipoma. Myelolipoma consists of a mature adipose tissue admixed with variable number of hematopoietic cells including megakaryocytes. Asterisk indicates the nonlesional adrenal cortex; arrows indicate multinucleated megakaryocytes.

lesions rarely contain true ovarian stromal elements, and are composed of fibroblastic and/or myofibroblastic mesenchymal cells. Some cases featuring radial scar-like appearance have also been defined.[17]

Adrenal Amyloidosis

Adrenal amyloidosis is a rare cause of adrenal insufficiency.[9] Affected individuals may exhibit adrenal enlargement, depending on the degree of the involvement. Histologically, amyloid deposition is characterized by a homogenous acellular pink hyaline material. It typically occurs in the wall of vascular structures, but also in the extracellular stroma between adrenocortical cells. The later results in diffuse replacement of cortical cells, depending on the extent of the disease. Special histochemical stains are frequently used to distinguish amyloid from fibrosis or stromal hyalinization, which can be identified in cortical nodular disease as well as in autoimmune adrenalitis.

Adrenal Calcification

Adrenocortical neoplasms and medullary tumors may contain dystrophic calcifications and even metaplastic bone formation. The nonneoplastic correlates of adrenal calcifications can be seen in the setting of infectious disease (e.g., histoplasma), adrenal cysts (see later), Wolman disease (lysosomal acid lipase deficiency) and GM1 gangliosidosis (β-galactosidase deficiency).[9,10,18,19] Wolman disease manifests with hepatosplenomegaly and infantile bilateral adrenal enlargement with dystrophic calcifications.[9,18] Necrosis and fibrosis can also occur. GM1 gangliosidosis presents with bilateral adrenal calcifications restricted to the medulla, given the accumulation of ganglioside in neuronal tissues.[10,19]

Adrenal Cysts

Primary adrenal cysts have four histologic variants, including (i) vascular (endothelial) adrenal cysts, (ii) epithelial adrenal cysts, (iii) parasitic adrenal cysts, and (iv) adrenal pseudocysts.[9,10,20] Most primary adrenal cysts are unilateral disease. Pseudocysts and vascular (endothelial) adrenal cysts are the most common subtypes that can simulate adrenocortical or medullary neoplasm.

Absence of epithelial or endothelial lining distinguishes adrenal pseudocysts from other types of adrenal cysts[9,20] (Fig. 91.4). These often have hemorrhagic, fibrinoid, or necrotic cyst content that can be mistaken for an adrenocortical carcinoma on imaging studies.[9,20] Vascular adrenal cysts are typically lined by endothelial cells that are commonly of lymphatic endothelial cell origin (Fig. 91.5). Vascular cysts may mimic pheochromocytomas. Epithelial cysts are lined by keratin-expressing cells of mesothelial origin (Fig. 91.6). Parasitic cysts occur in the course of parasitic adrenal infections (e.g., hydatid disease). Adrenal cysts should be distinguished from other adrenal lesions that can manifest with cystic degeneration, including adrenocortical neoplasms, pheochromocytomas, and neuroblastic tumors, as well as some metastatic carcinomas. Beckwith–Wiedeman syndrome can also show hemorrhagic multiloculated adrenal cysts in the background of adrenal enlargement.

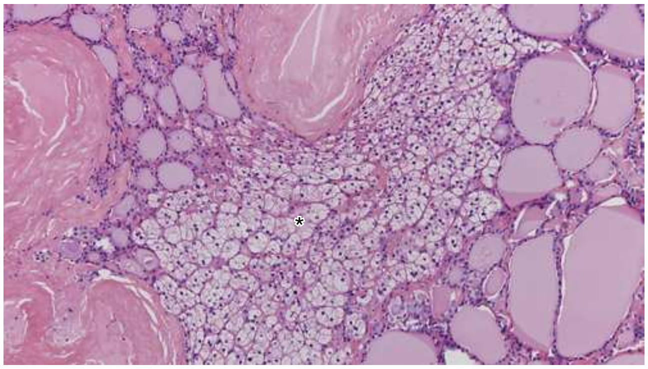

Fig. 91.3 Ectopic thyroid tissue in the adrenal. Adrenal gland can host ectopic thyroid tissue. The lack of cytological and architectural atypia warrants a diagnosis of benign ectopic thyroid tissue. The asterisk indicates the nonlesional adrenocortical cells in the zona fasciculata.

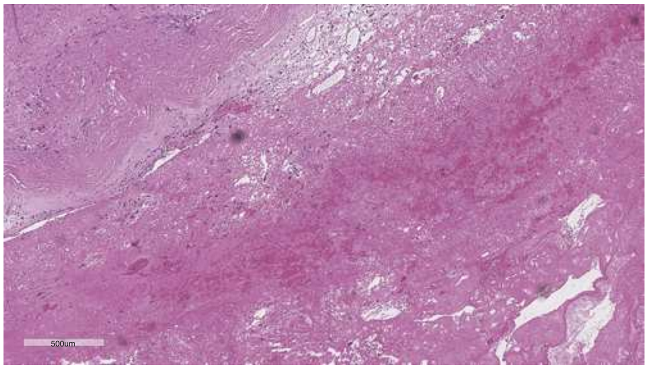

Fig. 91.4 Adrenal pseudocyst. Adrenal pseudocysts have no lining and are composed of hemorrhagic fibrinoid material.

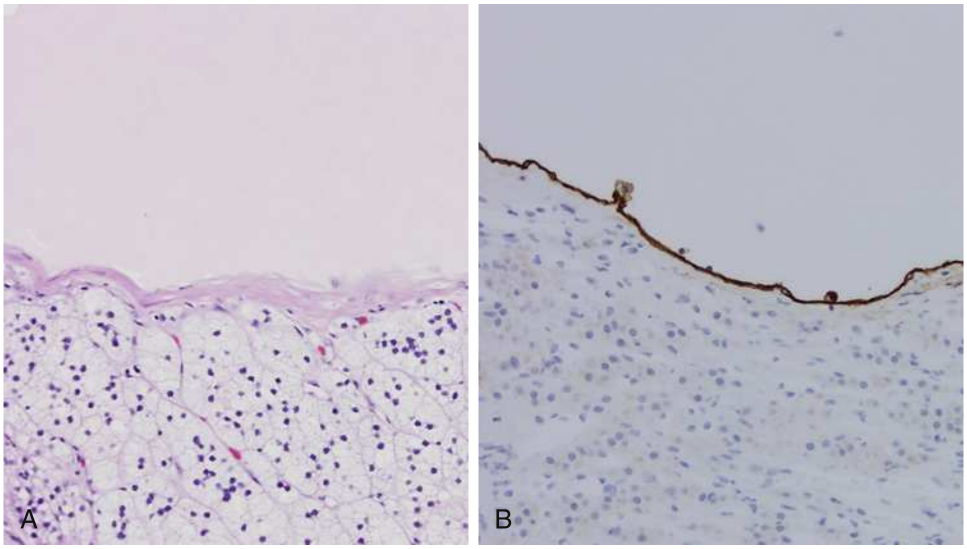

Fig. 91.5 Vascular (endothelial) cyst of the adrenal. This composite photomicrograph illustrates a vascular cyst surrounded by nonlesional adrenocortical cells (A). The lumen is acellular (A). CD31 (not illustrated herein) and D2-40 stain the vascular endothelial lining of this cyst (B).

Adrenal Infection and Abscess

Primary adrenal infection is a rare clinical presentation, because most develop as a result of widespread or locoregional infections.[9,10,21-24] Immunocompromised individuals have an increased risk of adrenal infection. On computed tomography (CT) scans, infection-related adrenal enlargement can be mistaken for an adrenal tumor because of a mass-like appearance or diffuse enlargement with variable heterogeneity.[21,22] Adrenal insufficiency (Addison disease) occurs, depending on the extent of tissue destruction.

Various microorganisms can cause adrenal infections. Parasitic infestations caused by *Echinococcus,* amebic species, *Trypanosoma, Leishmania,* and *Microsporidia* have been reported in adrenals.[9,23] Parasites can manifest with adrenal cystic disease (e.g., hydatid disease).

Among fungal pathogens, *Cryptococcus* and *Histoplasma* are the most common pathogens in nontropical geography, whereas *Paracoccidioides* predominates tropic geographic zones.[9,10,23,25] Histologically, necrotizing granulomatous inflammation is common in fungal infections. Enlargement of the adrenal glands with extensive adrenal destruction in association with extensive caseous necrosis and calcification is a feature of disseminated *Histoplasma* infection[9,23] (Fig. 91.7). In addition to cultures, histochemical stains (periodic acid–Schiff and Grocott's methenamine silver stains) are used to confirm fungal elements.

Immunocompromised hosts are more likely to develop viral adrenal infections. Among these, cytomegalovirus (CMV)-related adrenalitis is well-recognized; however, other viruses can also involve adrenal glands.[9,23] Unlike fungal and mycobacterial infections, adrenals show no marked enlargement in viral infections. Mixed inflammation in the corticomedullary junction and/or hemorrhagic necrosis (more frequent in *Herpesviridae*) can be seen.[9,10,24] Demonstration of viral cytopathic changes (e.g., Cowdry type A inclusions in CMV) confirms the diagnosis of a viral adrenal infection. Immunohistochemical antibodies against viral antigens are also very useful in the detection of viral antigens.

Bacterial adrenal infections typically occur either due to mycobacteria infections (e.g., immunocompromised or tuberculosis reactivation) or in the context of hematogenous spread in bacterial

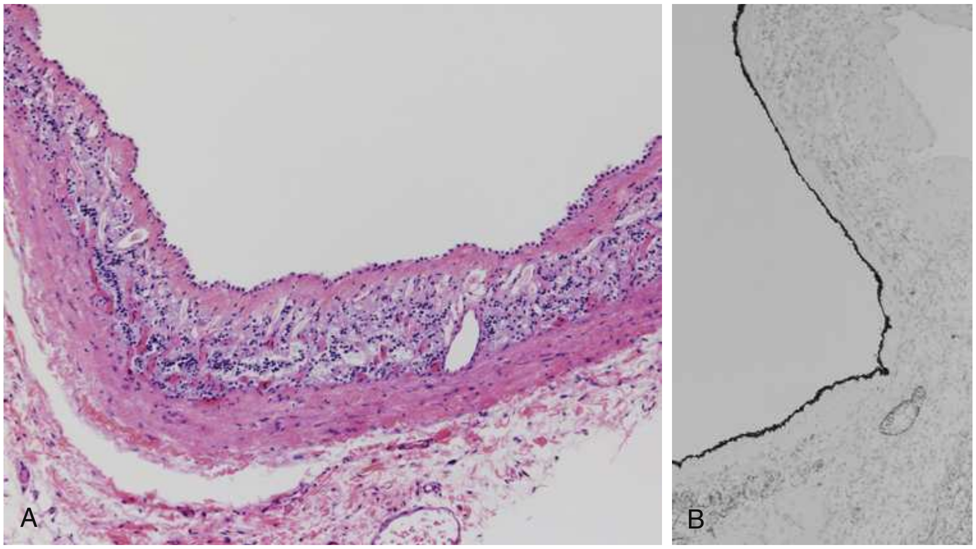

Fig. 91.6 **Epithelial cyst of the adrenal.** This composite photomicrograph illustrates an epithelial cyst surrounded by nonlesional adrenocortical cells (**A**). Pankeratin stains the lining of this cyst, as well as some cortical cells (**B**).

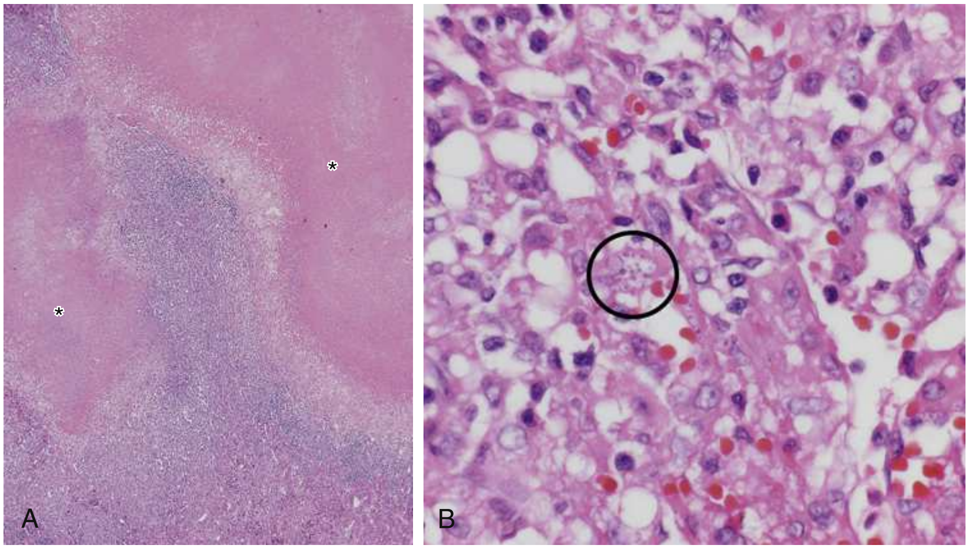

Fig. 91.7 **Histoplasma infection in the adrenal.** This composite photomicrograph illustrates a necrotizing granulomatous inflammation (**A**). Asterisks indicate the necrotic center of granulomatous inflammation. Some macrophages in the lesion contain multiple fungi, consistent with *Histoplasma* (**B**). Circled area represents fungal elements on hematoxylin and eosin–stained sections.

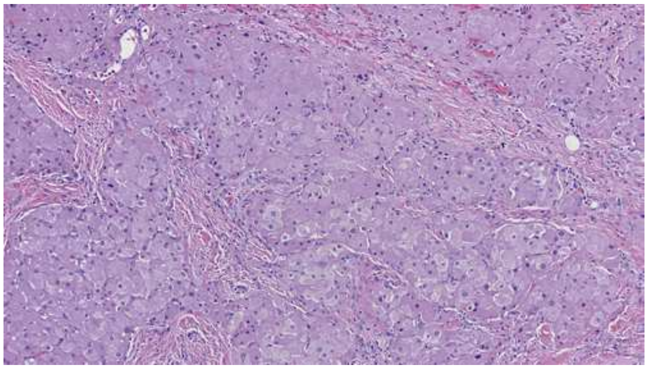

Fig. 91.8 **Congenital adrenal hyperplasia.** Bilateral compact (lipid-poor) cell adrenocortical hyperplasia is a characteristic morphologic feature of this disorder.

sepsis (e.g., *Streptococcus, Haemophilus, Staphylococcus, Meningococcus, Escherichia, Pseudomonas,* and *Klebsiella*).[9] Bacterial adrenal infections can manifest with adrenal enlargement, hemorrhage, necrosis, abscess, and malakoplakia.[9] Abscess occurs as a result of hematogenous spread of bacterial pathogens. Unilateral adrenal abscess can be mistaken for a tumor. Adrenal malakoplakia is a rare tumor-like inflammatory condition caused by gram-negative bacteria. Histologically, large collections of foamy macrophages with intracytoplasmic basophilic inclusions (Michaelis–Gutmann bodies) are characteristics features of malakoplakia. Waterhouse–Friderichsen syndrome refers to bilateral adrenal hemorrhage and necrosis that is caused by bacterial sepsis. Historically, mycobacterium tuberculosis has been recognized to account an important etiology of Addison disease.[9,10] Bilateral marked adrenal enlargement with variable degree of necrotizing granulomatous inflammation is a frequent finding in mycobacterial adrenal infections. Special histochemical stains (e.g., Ziehl–Neelsen) are required to visualize acid-fast bacilli in the cytoplasm of macrophages. However, histochemical stains fail to detect a very low number of bacteria; therefore, tissue cultures, PCR studies, and interferon-gamma release assays such as QuantiFERON have been frequently used as the golden standards in the distinction of mycobacterial infection (including the latent infection), as well as for the accurate characterization of mycobacteria.

Congenital Adrenal Hyperplasia

Defects in the enzymes involved steroid hormone biosynthesis cause CAH. Most common forms have been linked to *CYP21*-related 21-hydroxylase deficiency.[9,10,24] Patients who are not adequately treated with exogenous steroids manifest with marked bilateral adrenal enlargement due to ACTH-driven bilateral diffuse compact cell adrenocortical hyperplasia[9,10,24] (Fig. 91.8). Heterotopic adrenocortical tissue can become hyperplastic in patients with CAH. These hyperplastic tissues often simulate neoplastic disease in various locations.

Adrenal Cytomegaly

Adrenal cytomegaly is characterized by variable amount of enlarged adrenocortical cells with pleomorphic hyperchromatic nuclei with or without pseudoinclusions. Adrenal cytomegaly is distinguished from viral cytopathic changes of adrenal CMV infections by the presence of a single eosinophilic nuclear inclusion that is typically surrounded by a clear halo (Cowdry A) in infected cortical cells.[9] Premature infants and neonates can display areas of adrenal cytomegaly.[9,24] This finding does not qualify as a precursor or malignant process, and adrenal cytomegaly often resolves within months or years. However, focal adrenal cytomegaly rarely persists in other age groups.

Bilateral adrenal gland enlargement due to cortical proliferations (usually adrenocortical hyperplasia) with prominent adrenal cytomegaly, hemorrhagic cortical cysts, and prominence of chromaffin cells of the adrenal medulla are characteristic features of Beckwith–Wiedemann syndrome (Fig. 91.9). This congenital overgrowth syndrome is caused by altered imprinting of genes in chromosome *11p15.5* and has also been regarded as a predisposing condition for adrenocortical carcinoma.[26]

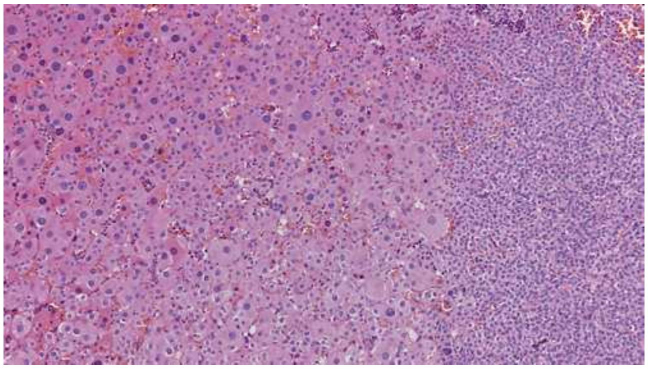

Fig. 91.9 **Adrenal cytomegaly in Beckwith–Wiedemann syndrome.** Bilateral adrenal gland enlargement due to cortical proliferations (usually adrenocortical hyperplasia) with prominent adrenal cytomegaly (cortical cells with enlarged nuclei) is one of the characteristic features of Beckwith–Wiedemann syndrome.

Inflammatory Adrenalitis

Focal adrenalitis is not an uncommon histologic finding, and it is often of no clinical significance. Noninfectious inflammatory changes are often seen in the context of autoimmune adrenalitis, which is typically seen in association with autoimmune polyglandular endocrinopathy types I and II[9,10] (Fig. 91.10). Depending of the disease stage, the cortex of both adrenals shows marked mixed chronic inflammation composed of lymphocytes, plasma cells, and macrophages.[9,10] The inflammatory adrenocortical destruction results in fibrohyalinization and small adrenal glands. The distinction of adrenalitis from a lymphoproliferative disorder is required when inflammation predominates the histology. Ancillary tools (e.g., immunohistochemistry and molecular pathology techniques) can be used to distinguish a lymphoproliferative disease from adrenalitis.

FUNCTIONAL APPROACH IN ADRENAL PATHOLOGY

The morphological spectrum of adrenal lesions includes hyperplastic and neoplastic disorders that are associated with hormonally active or nonfunctional "silent" clinicopathologic manifestations. Hormonally active adrenocortical lesions can cause mineralocorticoid excess (primary aldosteronism), glucocorticoid excess (adrenal Cushing syndrome and subclinical adrenal Cushing syndrome), sex hormone excess (virilism and feminization), and a combination of the these hormones excess syndromes.[9,27] Adrenal medullary lesions are often functional and result in catecholamine excess–related clinical signs and symptoms.

KEY POINTS

- Adrenocortical lesions are classified into three diagnostic morphological categories: (1) adrenocortical hyperplasia, (2) benign adrenocortical neoplasm, which includes adrenocortical adenomas and adrenocortical nodular disease, and (3) adrenocortical carcinoma. Micronodular and macronodular forms of adrenocortical nodular disease and diffuse adrenocortical hyperplasia are almost always functional disorders involving both adrenal glands. Nonfunctional lesions of the adrenal gland are more frequent in a subset of adrenocortical neoplasms that are enriched in Wnt pathway alterations.[28,29]

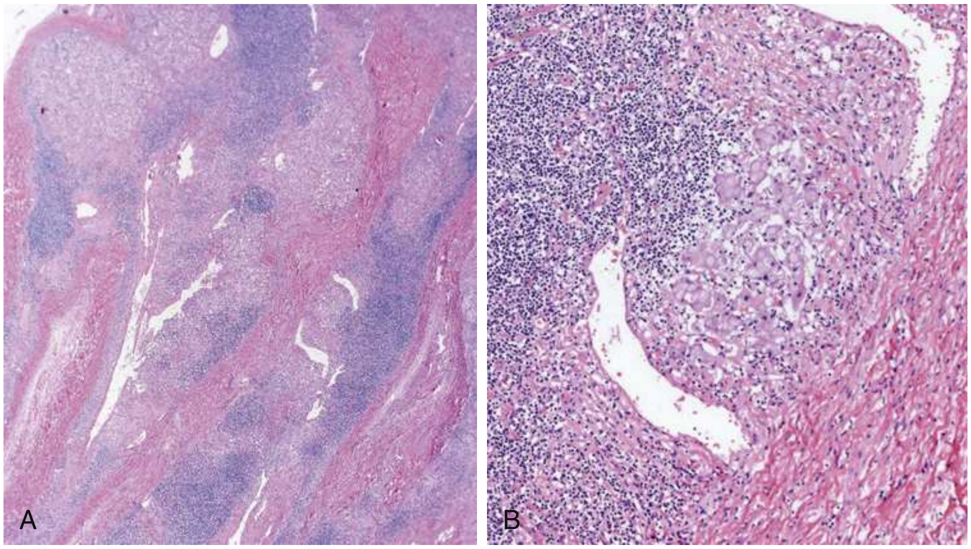

Fig. 91.10 **Inflammatory adrenalitis.** This composite photomicrograph illustrates marked mixed chronic inflammation composed of lymphocytes, plasma cells, and macrophages (A). The inflammatory adrenocortical destruction results in fibrohyalinization (A, B).

KEY POINTS

- The endocrine lesions of the adrenal medulla can be divided into two morphological categories: (1) adrenal medullary hyperplasia and (2) pheochromocytoma (adrenal paraganglioma). Pheochromocytomas are frequently associated with mature (adrenergic or mixed adrenergic and noradrenergic); however, immature (dopaminergic, noradrenergic, or mixed dopaminergic and noradrenergic) secretory biochemical phenotypes can also be identified.[30]

This section will provide a brief overview of the morphological entities that are reflected in functional adrenal disease. The details on molecular correlates of these lesions[29] are discussed in several other chapters of this book.

Pathological Correlates of Primary Aldosteronism

Discovery of ion channel mutations that result in the transcription of *CYP11B2* (encoding aldosterone synthase [CYP11B2]), occurrence of aldosterone-producing microscopic adenoma(s) that cannot be identified on CT imaging studies from patients with uniglandular disease, and application of CYP11B2 immunohistochemistry in adrenals from patients with primary aldosteronism have helped diagnosticians to better appreciate the clinicopathologic manifestations of primary aldosteronism.[29,31-34] The current evidence suggests that aldosterone-producing cortical lesions encompass a wide spectrum of lesions that range from microscopic to gross disease that can manifest with unifocal or multifocal disease with synchronous or asynchronous contralateral gland involvement.[29]

Traditionally, the most common clinical manifestation of primary aldosteronism is thought to represent bilateral hyperplasia of the zona glomerulosa[27,33]; however, the latter also includes bilateral microscopic aldosterone-producing adrenocortical adenomas that are not detected on imaging studies.[29] Bilateral diffuse zona glomerulosa hyperplasia is uncommon in the pathologist's practice, because affected patients often do not require bilateral adrenalectomy, but instead are treated with lifelong antimineralocorticoid therapy. Among neoplastic correlates of this disorder, aldosterone-producing carcinomas are extremely rare. As a consequence, aldosterone-producing benign cortical neoplasms account for most of the diagnoses of primary aldosteronism in the pathologist's practice (Fig. 91.11).

Aldosterone-producing adrenocortical adenomas show cytomorphological and epidemiological heterogeneity with respect to their underlying somatic mutations (Table 91.1).[29,32] For instance, aldosterone-producing adenomas that harbor *KCNJ5* mutations are enriched in lipid-rich zona fasciculata–type cortical cells. These tumors are more frequent in females, and are often solitary large tumors.[29,32] In contrast, adenomas that are associated with a nonmutated *KCNJ5* gene are enriched in compact cortical cells in the setting of multifocal disease with smaller tumor sizes when compared with *KCNJ5*-related disease. These tumors are also reported to be more frequent in males.[29,32]

The preoperative prediction of bilateral disease is still an ongoing challenge in the clinical management of patients with primary aldosteronism. Despite continued efforts to effectively preoperatively lateralize unilateral aldosterone excess via adrenal venous sampling, biochemical recurrence can still occur in such cases. Recently, genotype–phenotype correlations (Table 91.1) have provided critical insights into the genetic and cellular features underlying unilateral versus bilateral disease. Furthermore, CYP11B2 immunohistochemical features underscore morphological findings that may help predict the potential risk for bilateral disease.[29,31,34] As a consequence, the modern endocrine pathology practice of primary aldosteronism requires a thorough cytomorphological examination of the entire adrenal gland. For example, in patients with preoperative spironolactone treatment, functional histologic foci can display variable amount of spironolactone bodies that may provide clues to multifocality and bilaterality of disease.[27,33] However, the accurate distinction of functional sites requires the use of CYP11B2 immunohistochemistry in adrenalectomy specimens.[31,32,34]

Mixed aldosterone and glucocorticoid secretion from an adrenocortical adenoma can occur. This manifestation is more frequent in a subset of adrenocortical neoplasms with *KCNJ5* mutations.[35,36] Unlike aldosterone-producing benign cortical disease, aldosterone-producing adrenocortical carcinomas lack ion channel mutations but display genetic alterations as seen in other adrenocortical carcinomas.[37]

KEY POINTS

- The HISTALDO classification[34] has been introduced by a group of international disease experts to provide a unified diagnostic nomenclature relevant to reporting of surgical pathological findings in adrenalectomy specimens from patients with unilateral primary aldosteronism.[34] The conventional histopathological examination and CYP11B2 staining patterns identified in adrenal nodules and the adjacent cortex form the basis of this classification system.

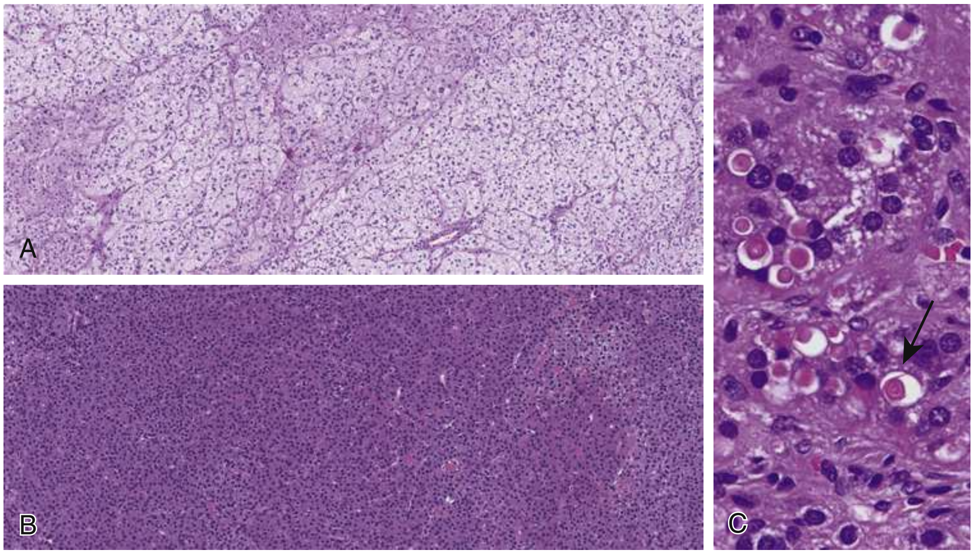

Fig. 91.11 **Aldosterone-producing adrenocortical adenoma (Conn syndrome).** The morphological heterogeneity in primary aldosteronism is reflected in this composite photomicrograph. Aldosterone-producing adenomas that harbor *KCNJ5* mutations are enriched in zona fasciculata–like clear cells (**A**), whereas *KCNJ5*–wild-type adenomas are enriched in zona reticularis– and zona glomerulosa–like cells (**B**). Patients treated with spironolactone often show tumor cells with eosinophilic lamellated inclusions that are also known as spironolactone bodies (**C**). The arrow indicates one of the many inclusions.

TABLE 91.1 Genotype–Phenotype Correlations in Primary Aldosteronism[29,32]

Molecular Subgroups	Gene(s)	Characteristics	Germline Variants*
***KCNJ5*-related PA**	*KCNJ5*	- Most frequent cause of PA - More frequent in females - Pronounced PA - Often earlier age of disease onset - Often unilateral disease - Often solitary or dominant adenoma - Enriched in ZF-like cortical cells - Higher *CYP17A1* and *CYP11B1* transcripts compared with *KCNJ5*–wild-type PA - Can feature cortisol cosecretion	FHA type III
***KCNJ5*–wild-type PA**	*ATP1A1* *ATP2B3* *ATP2B4*** *CACNA1H* *CACNA1D* *CLCN2*	- More frequent in males - Often less pronounced PA - Often later age of disease onset - Germline pathogenic *CACNA1H* and *CACNA1D* variants manifest with early age of disease onset - Smaller tumor size; increased frequency of multifocal disease - Increased risk of recurrence - Enriched in ZG- and ZR-like compact cells - Increased CYP11B2 to CYP11B1 ratio - With the exception of *CLCN2*-mutant tumors, lower levels of *CYP17A1* and *CYP11B1* expression - Higher levels of CYP11B2 mRNA transcripts compared with *KCNJ5*-related disease	FHA type II: *CLCN2* FHA type IV: *CACNA1H* PASNA syndrome: *CACNA1D* *ATP2B4* variants
***CTTNB1*-related PA**	*CTTNB1*	- Rare cause of PA (~5% of PA) - More frequent in females - Often later age of disease onset - Higher risk of recurrence - Heterogenous cytomorphology - Heterogenous CYP11B2 expression - Nuclear and cytoplasmic beta-catenin	

*Germline pathogenic variants that can be seen in this molecular subgroup.

**Rare germline variants.

PA, Primary aldosteronism; ZF, zona fasciculata; ZG, zona glomerulosa; ZR, zona reticularis; FHA, familial hyperaldosteronism; PASNA syndrome, early onset of primary aldosteronism with seizure and neurological abnormalities.

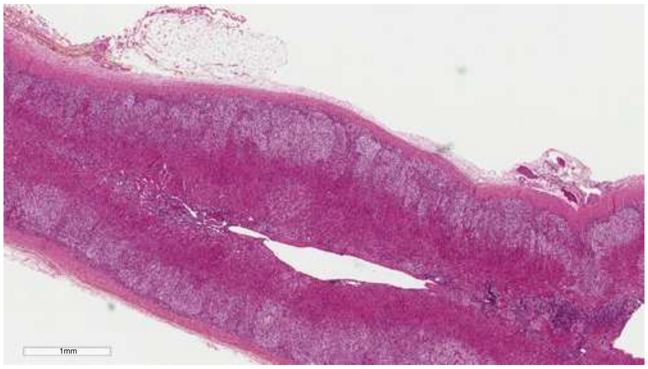

Fig. 91.12 **Pituitary ACTH-related diffuse adrenocortical hyperplasia.** Pituitary ACTH-related diffuse adrenocortical hyperplasia is associated with bilateral adrenal gland enlargement. While zona reticularis is slightly expanded, all three cortical zones are preserved.

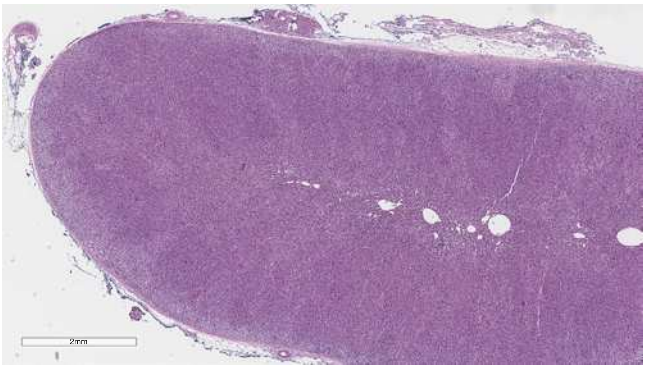

Fig. 91.13 **Ectopic adrenocorticotropic hormone (ACTH)-related diffuse adrenocortical hyperplasia.** Unlike the pituitary ACTH-related pathogenesis, the adrenocortical zonation is not preserved. The adrenal cortex in both adrenals show a lipid depletion pattern.

HISTALDO Classification

Aldosterone-producing carcinoma (APACC)

CYP11B2-expressing adrenocortical carcinoma

Aldosterone-producing adenoma (APA)

CYP11B2-expressing solitary benign adrenocortical neoplasm (≥1.0 cm)

Aldosterone-producing nodule (APN)

CYP11B2-expressing subcentimeter benign adrenocortical nodular disease; CYP11B2 staining is often stronger at the periphery

Aldosterone-producing micronodule (APM)

CYP11B2-expressing subcentimeter microscopic cortical proliferation consisting of zona glomerulosa–like cells that tend to display a gradient staining as seen in APN

Multiple aldosterone-producing nodules (MAPN) or multiple aldosterone-producing micronodules (MAPM)

Aldosterone-producing diffuse hyperplasia (APDH)

CYP11B2-expressing nonnodular broad or continuous zona glomerulosa–layer hyperplasia that accounts for >50% of the zona glomerulosa layer

The pathological correlates of adrenal Cushing syndrome

(v) **Diffuse adrenocortical hyperplasia**
  a) ACTH dependent (Pituitary, ectopic)
  b) CRH dependent (Hypothalamic, ectopic)
(vi) **Bilateral nodular adrenocortical disease**
  c) Micronodular form
  d) Macronodular form
(vii) **Adrenocortical adenoma**
(viii) **Adrenocortical carcinoma**

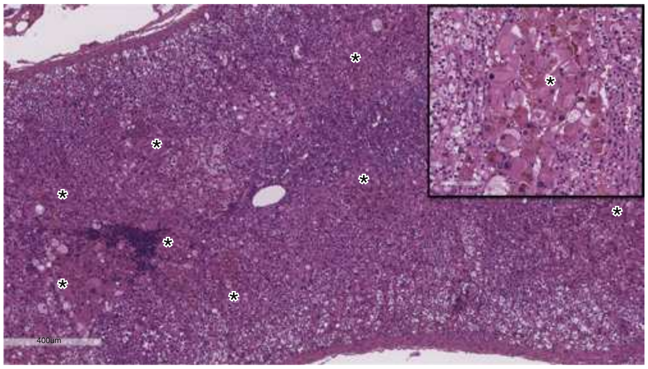

Fig. 91.14 **Primary bilateral micronodular adrenocortical disease.** Both adrenal glands are slightly enlarged and contain compact cell–rich micronodules that are variably pigmented. The illustration is from an individual with primary pigmented nodular adrenocortical disease. Asterisks indicate micronodules.

Pathological Correlates of Adrenal Cushing Syndrome

Diffuse adrenocortical hyperplasia is the only “true hyperplastic” disorder of the adrenal cortex in patients with Cushing syndrome (Fig. 91.12). The latter also accounts for the most frequent cause of endogenous Cushing syndrome.[32,38] From a pathogenic perspective, ACTH-dependent disease is due to functional pituitary corticotroph tumor in the vast majority of patients.[9,32,38] However, ectopic ACTH or corticotropin-releasing hormone (CRH) production in neuroendocrine neoplasms,[27,38] and CRH-producing hypothalamic tumors[39] can also result in diffuse adrenocortical hyperplasia. At the morphologic level, the adrenal cortex in both adrenal glands is expanded with preserved adrenocortical zonation in the setting of pituitary ACTH-dependent pathogenesis. Endocrine pathologists can distinguish pituitary ACTH-dependent diffuse hyperplasia from ectopic ACTH-related diffuse hyperplasia, because in the latter the lack of cortical zonation and the presence of prominent zona reticularis–like compact cell hyperplasia result in lipid depletion pattern that gives an appearance that is often referred to “pink adrenal cortices”[9,27] (Fig. 91.13).

Bilateral nodular adrenocortical disease consists of two clinicopathologically significant forms, including (i) primary bilateral micronodular adrenocortical disease (Fig. 91.14) and (ii) primary bilateral macronodular adrenocortical disease (Fig. 91.15) (Table 91.2). At the morphological level, the distinction between the two forms is made based on the size of the cortical nodules. The micronodular forms consists of bilateral small cortical nodular proliferations (measuring less than 1.0 cm; usually ranging in size from 0.1 to 0.4 cm). The micronodules are enriched in compact (lipid-poor) cortical cells that can be pigmented in some cases (e.g., primary pigmented nodular adrenocortical disease) (Fig. 91.14). These are often located in the deep zona fasciculata and/or zona reticularis.[27,29,32] In contrast to micronodular forms of this disease, the macronodular forms are almost always

KEY POINTS

- Traditional diagnostic terminologies such as primary micronodular or macronodular hyperplasia of the adrenal cortex are no longer credible nomenclatures for primary bilateral nodular forms of adrenocortical disease, because those nodules are composed of genetically transformed adrenocortical cells; therefore, modern endocrine pathology practices classify them within the spectrum of adrenocortical neoplasia, and they are referred to as bilateral nodular adrenocortical disease.[27,29]

associated with significantly enlarged adrenals that are composed of several nodules that generously exceed 1.0 cm in size. The nodular proliferations are enriched in zona fasciculata–like clear cells, but variations in cytomorphological findings can occur[27,32] (Fig. 91.15).

The distinction of primary bilateral nodular adrenocortical disease in Cushing syndrome is of clinical significance given the increased frequency of germline susceptibility in both micro- and macronodular forms of this manifestation.[27,29,32,38]

Cortisol-producing adrenocortical adenomas are often unilateral and solitary neoplasms. At the morphological level, they can display cytomorphological heterogeneity; however, most are composed predominantly of zona fasciculata–like lipid rich cortical cells.[9,27,32,38] Oncocytic change and pigmentation can feature in some examples.[9,32] Cortisol-producing adenomas are distinguished from ***cortisol-producing adrenocortical carcinomas*** using multiparameter scoring systems and ancillary tools[9,27] that are summarized later in this chapter.

At a molecular level, autonomous overt cortisol excess from adrenal neoplasms (e.g., cortisol-producing adrenocortical adenomas and bilateral micronodular adrenocortical disease) are often associated with protein kinase A pathway activation,[27,29,32,38] which has also been correlated with high expression of the *DLK1-MEG3* miRNA in a recent genomic studies.[28] Most patients with primary macronodular adrenocortical disease have been linked to *ARMC5*-driven pathogenesis[27-29,41] that is also correlated with global CpG hypermethylation status and an ovarian gene expression signature in a recent genomic studies[28]; however, rare examples of primary macronodular disease have been reported in association with *MEN1*, *FH*, *GNAS*, *PDE8B*, *PDE11A*, and *PRKACA* variants.[29,32,38] Adrenocortical adenomas causing mild autonomous cortisol excess (subclinical Cushing syndrome) frequently harbor *CTNNB1* mutations and chromosome 17q losses.[28]

KEY POINTS

- From a functional histopathology approach, the nontumorous adrenocortical atrophy is a reliable sign of autonomous glucocorticoid secretion from an adrenocortical neoplasm in patients with no history of exogenous glucocorticoid administration (Fig. 91.16). Therefore, assessment of the nontumorous adrenal cortex is a critical responsibility of pathologists to prevent an Addisonian crisis, especially in patients with unrecognized mild autonomous glucocorticoid-secreting adrenocortical neoplasms.[9,27,40]

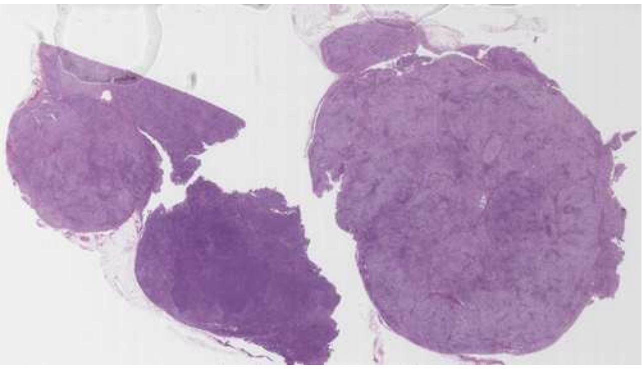

Fig. 91.15 Primary bilateral macronodular adrenocortical disease. Both adrenal glands are significantly enlarged due to multiple benign cortical nodules; each nodule exceeds 1 cm.

Pathological Correlates of Virilism/Feminization

KEY POINTS

- In both adult and pediatric age groups, the identification of virilism/feminization due to an adrenal mass requires exclusion of a functional adrenocortical carcinoma,[9,27] most of which tend to cosecrete glucocorticoids.

Rare examples of testosterone-producing adrenocortical adenomas have been reported in adults.[42] Unlike adults, this phenomenon has been relatively more frequently reported in pediatric adrenocortical adenomas,[43-46] including some examples, especially oncocytic adrenocortical adenomas, that feature synchronous virilization and adrenal Cushing syndrome.[44,45] Given the well-known challenges in the distinction of malignant behavior in adrenocortical neoplasms[47] and the fact that this functional group is more frequent in adrenocortical

TABLE 91.2 Clinicopathological Features of Primary Bilateral Nodular Adrenocortical Disease[27-29,32]

Pathology	Gene Alterations or Variants	Characteristics
Primary bilateral micronodular adrenal cortical disease - PPNAD - MAD	*PRKAR1A* *CNC2 locus/2p16* *PDE11A* *PDE8B* *PRKACA* *PRKACB* *ARCM5**	- Bilateral multiple compact cell small nodules ranging in size from 0.1 to 0.4 cm - Nodules are located in the zona fasciculata layer or in the intersection of zona fasciculata and reticularis layers - PPNAD is distinguished histologically from MAD based on the presence of pigmented micronodules - PPNAD may be associated with Carney complex - Bead-like appearance of micronodules on imaging studies - Internodular cortex shows atrophy in PPNAD - *PRKAR1A*-related pathogenesis is associated with an earlier age disease onset compared to *CNC2* locus-related pathogenesis - Paradoxical response on Liddle's test
Primary bilateral macronodular adrenal cortical disease	*ARMC5* *MEN1*** *FH*** *APC*** *PDE8*** *PDE11A*** *PRKAR1A*** *PRKACA***	- Marked bilateral enlargement of adrenals - Multiple clear cell–rich clonal nodules exceeding 1.0 cm - Childhood-onset disease shows more pronounced Cushing syndrome compared with adult-onset disease - *ARCM5*-related disease is more common in adults - *ARMC5*-related disease shows significantly more enlargement of adrenals with more nodularity and hypercortisolism compared with *ARMC5*–wild-type disease - Ovarian gene expression signature (*FOXL2, CYP19A1, PTHLH*) and global CpG hypermethylation

*Rare missense variant.

**Rare events; can be more frequent in childhood manifestations.

PPNAD, Primary pigmented micronodular adrenocortical disease; *MAD*, micronodular adrenocortical disease.

carcinomas,[48] one should still be careful when rendering a diagnosis of adenoma in this setting. The morphological criteria that help distinguish adrenocortical carcinoma and ancillary tools available to diagnosticians are discussed later in this chapter.

Pathological Correlates of Catecholamine Excess

KEY POINTS

- *Pheochromocytoma* (adrenal paraganglioma) is the most common pathological correlate of catecholamine excess from the adrenal gland.

At the morphological level, these tumors are no different than their extraadrenal counterparts, which are termed as paragangliomas. They display heterogenous cytology (e.g., conventional, clear cell, oncocytic) and growth patterns (e.g., Zellballen-like small nests, solid diffuse, trabecular, large confluent nests, cystic) (Figs. 91.17 and 91.18).

The term *composite pheochromocytoma* is applied to pheochromocytomas that are admixed with composite elements, including neuroblastoma, ganglioneuroblastoma, ganglioneuroma, and peripheral nerve sheath tumor (Fig. 91.19). Pathologists are required to determine the presence/absence of composite elements.

Adrenal medullary hyperplasia is restricted to diffuse expansion of the adrenal medulla that exceeds one third of the adrenal gland thickness or when adrenal medulla is identified in the tail of the adrenal gland.[49-51] In the past, microscopic adrenal medullary nodules measuring less than 1.0 cm were referred to as nodular medullary hyperplasia; however, the latter is no longer accepted. Any distinct microscopic nodules (<1.0 cm) in the adrenal medulla are now considered clonal disease; thus, the term "micropheochromocytoma" is applied[49-51] (Fig. 91.20).

The distinction of pheochromocytoma from adrenocortical pathologies is of clinical significance. This tumor family, paraganglioma and pheochromocytoma, has the highest germline susceptibility among all tumors.[50,51] The biochemical status of the tumor, the cytomorphology of the tumor and its surrounding stroma, the presence or absence of associated composite elements or adrenal medullary hyperplasia, and molecular immunohistochemistry (see below the section on diagnostic and predictive immunohistochemical biomarkers in adrenal pathology) help endocrine pathologists in the distinction of various forms of inherited pheochromocytomas.[51] For instance, *VHL*-related pheochromocytomas are often encapsulated and show clear cell change with stromal degeneration and increased microvasculature[50-53] (Fig. 91.21). Succinate dehydrogenase subunit (*SDHx*)-mutant tumors often show tumors cells with variable cytoplasmic vacuoles[50,51,54] (Fig. 91.22). Multifocal and/or bilateral pheochromocytomas are almost always a sign of germline disease, and the latter occurs more frequently in the setting of germline *RET* and *VHL* disease.[51,53] Composite elements

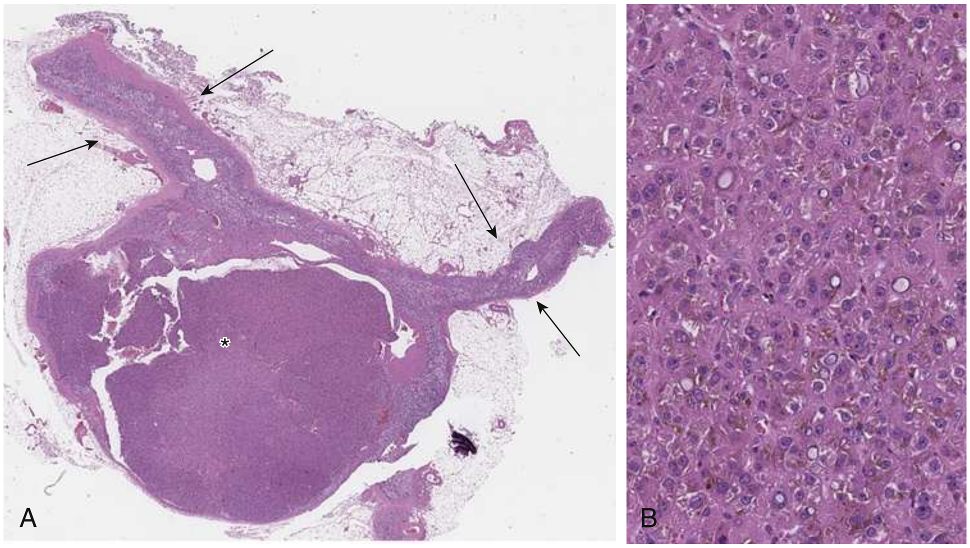

Fig. 91.16 **Cortisol-producing adrenocortical adenoma.** This composite photomicrograph illustrates a cortisol-producing adrenocortical adenoma (**A**, **B**). The tumor cells are variably pigmented (**B**). The asterisk indicates the tumor substance (**A**). There is marked atrophy of the nontumorous cortex *(arrows)*.

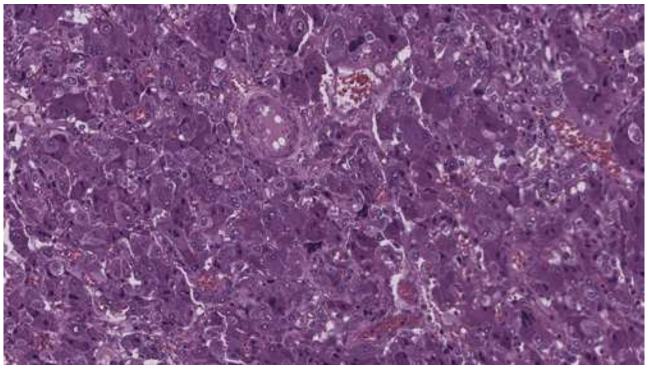

Fig. 91.17 **Pheochromocytoma.** This figure represents a conventional pheochromocytoma that is composed of tumor cells with basophilic granularity due to mature catecholamine granules.

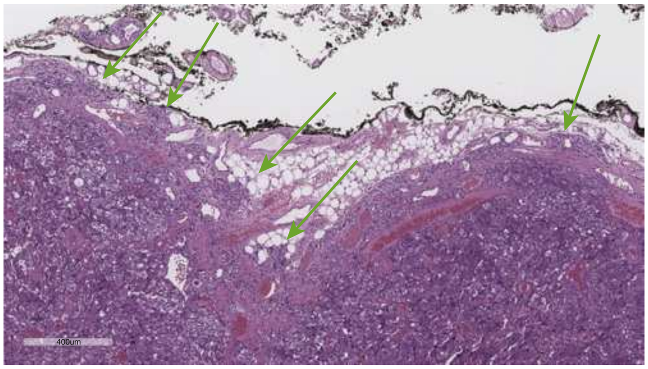

Fig. 91.18 **Invasive growth in pheochromocytoma.** Pheochromocytomas are not benign neoplasms, and they harbor lifelong metastatic potential. The status of invasive growth can be appreciated in a fraction of these tumors. The arrows illustrate multifocal microscopic tumor extension into the periadrenal adipose tissue.

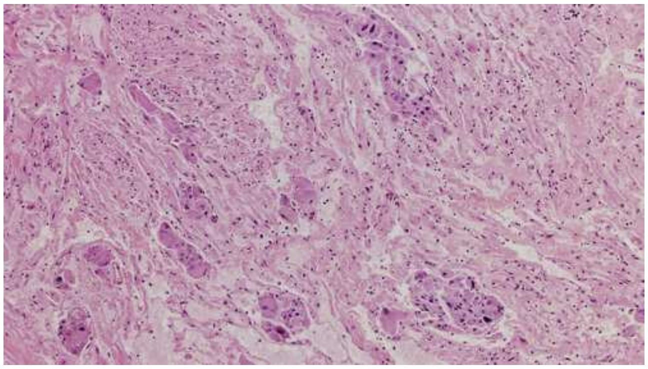

Fig. 91.19 Composite pheochromocytoma. This composite pheochromocytoma consists of ganglioneuroma and pheochromocytoma.

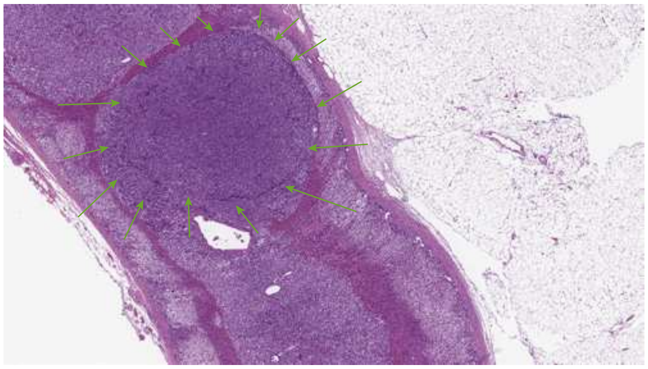

Fig. 91.20 Micropheochromocytoma. This photomicrograph illustrates a micropheochromocytoma *(arrows)* characterized by micronodular proliferation in the background of germline *RET*-driven diffuse adrenal medulla hyperplasia. Nodular hyperplasia of the adrenal medulla is not accepted terminology for distinct adrenal medullary micronodules.

can be seen in *NF1*- and *MAX*-related disease.[51 55] Adrenal medullary hyperplasia may be a harbinger of germline *RET, TMEM127, MAX,* and *SDHx*-related pathogenesis.[49-51,56-58]

KEY POINTS

- All paragangliomas and pheochromocytomas are malignant non-epithelial neuroendocrine neoplasms. These tumors have metastatic potential depending on their risk category.

Several multiparametric scoring systems (e.g., Pheochromocytoma of the Adrenal gland Scaled Score [PASS], Grading system for Adrenal Pheochromocytoma and Paraganglioma [GAPP], modified GAPP, and COmposite Pheochromocytoma/Paraganglioma Prognostic Score [COPPS] systems)[59,60-62] have been introduced in an attempt to predict the risk of metastasis. However, no single system is highly reproducible, and none have been endorsed by the World Health Organization (WHO) classification system of endocrine tumors. A recent metaanalysis series underscored the negative predictive value of low scores in the distinction of the low-risk disease.[63] Nevertheless, a dynamic risk stratification that combines several clinicopathologic parameters is more commonly adopted in modern endocrine oncology practices. The large tumor size (often >5.0 cm), immature secretory phenotype (e.g., dopaminergic, noradrenergic, or mixed dopaminergic and noradrenergic), tumor necrosis, increased proliferation (e.g., Ki67 labeling index >3%), and molecular characteristics (e.g., somatic *MAML3* fusions or *CSDE1* alterations related to altered Wnt-pathway clusters, *SDHB*-related pseudohypoxic pathway disease, select alterations in the kinase signaling pathway, and somatic *SETD2*, *ATRX,* and *TERT* alterations) are considered important risk factors in dynamic risk stratification.[60,64-68]

Although molecular testing for germline screening is now standard care in the management of patients with pheochromocytomas and paragangliomas, routine molecular testing for somatic alterations is still not the standard of endocrine pathology practice, even in most advanced practices.

PATHOLOGY IN THE DISTINCTION OF ADRENOCORTICAL CARCINOMA

Adrenocortical carcinoma is defined as a malignant epithelial tumor of adrenocortical cells.[69] These are rare tumors comprising less than 3% of endocrine tumors and affect all ages, but are more common in those 40 to 50 years of age. Adrenocortical carcinomas affect females more commonly than males. Approximately half of these tumors are functional, and functional tumors are more commonly seen in females.

Adrenocortical carcinomas are usually large tumors, often 10 cm or greater in size, but the size can vary greatly from 1 cm up to 30 cm or more. Size alone is a significant feature in adrenocortical neoplasms. Adrenocortical neoplasms weighing 50 g or more are of concern, and those weighing 100 g or more are of very significant concern by size in weight alone. However, adrenocortical carcinomas weighing less than 50 g can occur, and the size and weight alone are not sufficient to differentiate benign from malignant adrenocortical neoplasms.

Adrenocortical carcinomas are usually solid and may show necrosis, but cystic adrenocortical carcinomas have been reported.[70] Adrenocortical carcinomas can also be myxoid (Fig. 91.23), and the behavior of these tumors may be more difficult to predict than in conventional adrenocortical neoplasms (Fig. 91.24).[71] The behavior of oncocytic adrenocortical tumors may also be difficult to predict by conventional classification; thus, a separate classification (the Lin–Weiss–Biscgelia system) is used for these tumors.[72,73] A separate classification system is also utilized in diagnosis of malignancy in adrenocortical neoplasms in children.[74]

Distinction of adrenocortical adenoma from carcinoma is generally straightforward (Figs. 91.23, 91.24, and 91.25). However, some cases can be extraordinarily difficult, as reflected in the numerous classification systems that have been proposed for the diagnosis of adrenocortical carcinoma.[75-78] In 1984, Dr. Weiss and colleagues evaluated 43 adult adrenocortical neoplasms with 5 years of follow-up for nine histologic parameters.[76] Eighteen of 19 tumors with a score of 4 or more were associated with recurrence or metastasis. All 24 tumors with a score of 2 or less were associated with benign outcome. They found no single feature that was diagnostic of malignancy. The most significant features were mitotic rate of greater than five per 50 high-power fields (10 mm^2), atypical mitoses, and vascular invasion (venous angioinvasion). In 1989, the Weiss score was lowered from 4 to 3, as a patient with a score of 3 had recurrent disease and died of disease.[77] Weiss and colleagues found that only mitotic rate had a significant association with outcome. Tumors with mitotic rate of greater than 20 per 50 high-power fields were regarded as high-grade and associated with a median survival of 14 months. Tumors with a mitotic rate of less than or equal to 20 per

Weiss system*

1. Fuhrman nuclear grade III or IV
2. Mitotic activity >5 per 50 high-power fields
3. Atypical mitotic figures
4. Clear cells ≤25% of the tumor volume
5. Diffuse architecture >30% of the tumor volume
6. Tumor necrosis
7. Venous angioinvasion
8. Lymphatic (sinusoidal) invasion
9. Capsular invasion

**Malignant: Score ≥3 out of 9 Applied only to nononcocytic and adult-onset tumors*

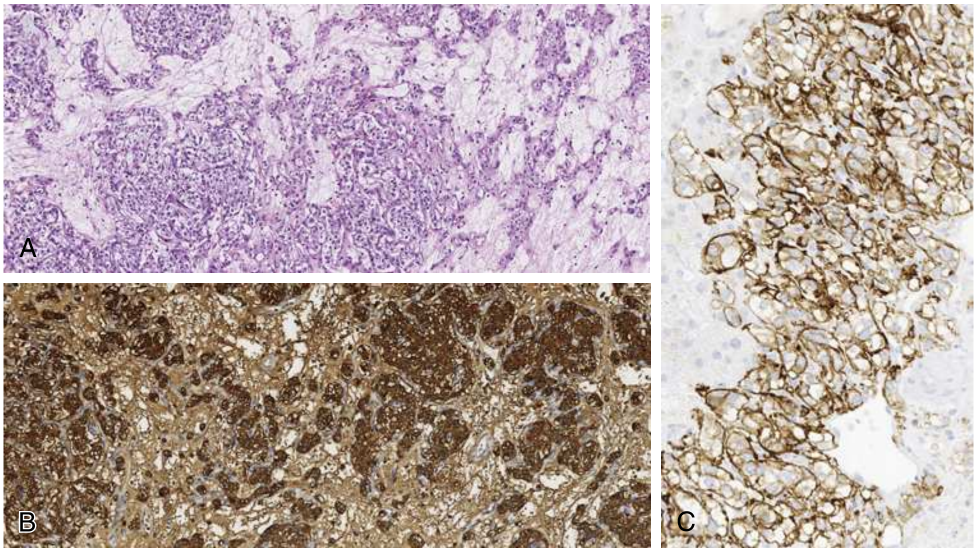

Fig. 91.21 ***VHL*-related pheochromocytoma.** VHL-related pheochromocytomas are often encapsulated tumors enriched in clear cells (**A**). Positivity for neuroendocrine markers (not illustrated herein) and tyrosine hydroxylase (**B**) distinguishes this tumor from a clear cell–rich adrenocortical neoplasm. Membranous carbonic anhydrase IX (**C**) expression is a feature of *VHL*-related pathogenesis.

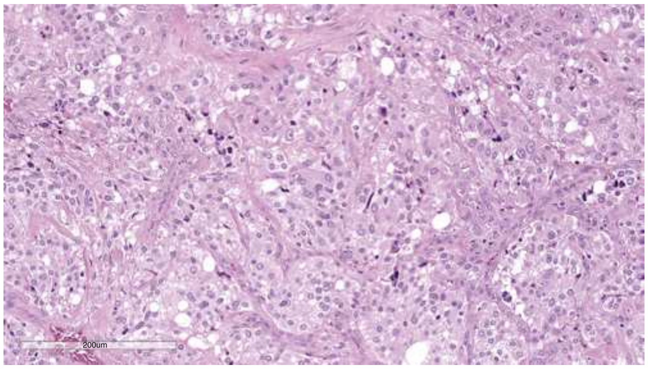

Fig. 91.22 **Morphology of *SDHx*-related pheochromocytoma.** *SDHx*-related tumors are composed of tumor cells with variable cytoplasmic eosinophilia and cytoplasmic vacuoles.

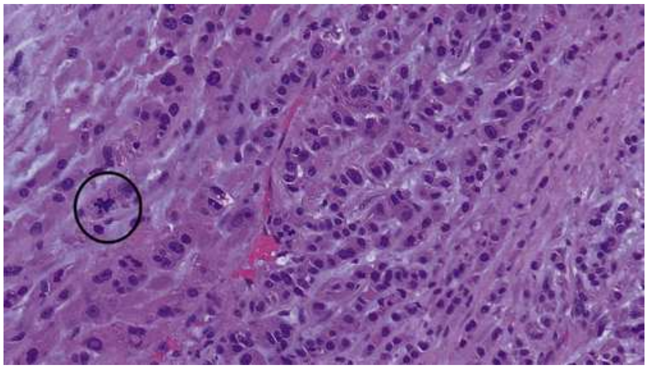

Fig. 91.23 **Myxoid change in adrenocortical carcinoma.** Myxoid change can obscure signs of malignancy; however, a detailed morphological assessment often helps in the distinction of carcinoma. Adrenocortical carcinomas are driven by proliferation. The circled area represents an atypical mitotic figure. This tumor had increased mitotic activity (>5 per 50 high-power fields), including several atypical mitoses.

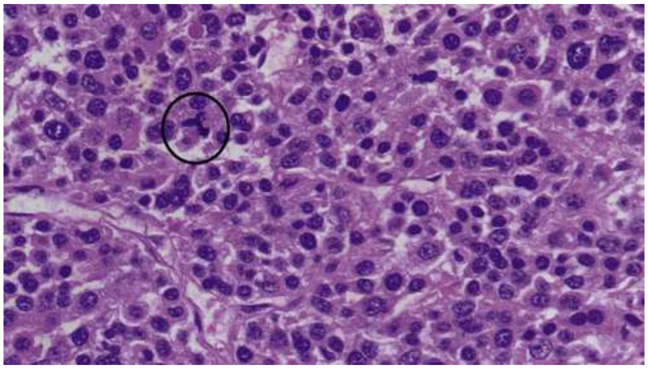

Fig. 91.24 **Conventional adrenocortical carcinoma.** Most adrenocortical carcinomas are composed of lipid poor cells that are arranged in sheets. A tripolar atypical mitotic figure (circled area) is illustrated in this photomicrograph.

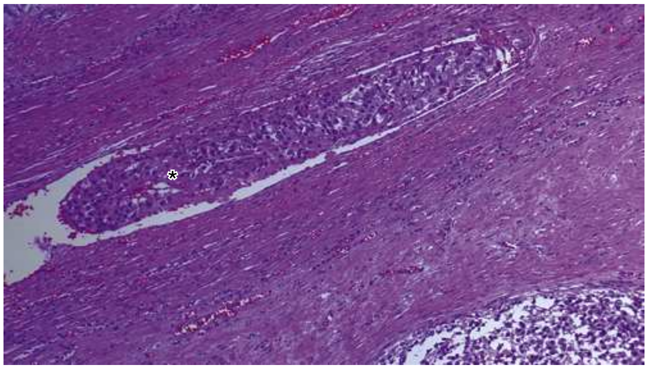

Fig. 91.25 **Vascular invasion in adrenocortical carcinoma.** The identification of a *bona fide* vascular invasion (venous angioinvasion) is not only a sign of malignancy but is also a prognostic factor for metastatic spread. The presence of intravascular tumor cells admixed with fibrin thrombus is illustrated *(asterisk)*.

50 high-power fields were regarded as low-grade, with median survival of 58 months.

Numerous other systems have been suggested previously and subsequently, but the system proposed by Weiss in 1984 and its subsequent modification in 1989 with three or more of the nine features as malignant remains the gold standard today.[77,79] In 2002, another modified Weiss system, or "Weiss revisited" system, suggested by matching functional status of 24 adrenocortical carcinomas with distant metastasis, gross local invasion, or recurrence with 25 benign tumors.[80] This is a modified system based on the most reliable criteria of the prior Weiss studies from 1984 and 1989, including mitotic rate of greater than five per 50 high-power fields, atypical mitotic figures, clear cells in less than or equal to 25% of the tumor, necrosis, and capsular invasion. A score of 3 or more out 7 in this study was considered diagnostic of malignancy. Still, the 1989 Weiss system remains the diagnostic standard for adult nononcocytic adrenocortical neoplasms.

Modified Weiss System*

- mitotic rate (score: 2)
- compact cytoplasm (score: 2)
- atypical mitoses (score: 1)
- necrosis (score: 1)
- capsular invasion (score: 1)

*Malignant: score ≥3 out 7

The "reticulin algorithm" evaluated disruption of the reticular network (highlighted by reticulin staining) (Fig. 91.26) and one or more of the following criteria (mitoses greater than five per 50 high-power fields, necrosis, or vascular invasion) in 92 carcinomas in 47 adenomas and found sensitivity and specificity of 100%.[81] Volante and colleagues found tumor stage III or IV and mitoses greater than nine per 50 high-power fields had a strong adverse impact on disease-free and overall survival, and were able to divide the tumors into three risk groups. A subsequent multicenter study in 2013 by Duregon and colleagues validated the reticulin algorithm in a study of 184 adrenocortical carcinomas and 61 adenomas.[82] The reticulin algorithm may be helpful in the evaluation of myxoid and oncocytic adrenocortical tumors. In a study by Mete and colleagues, loss of the reticulin framework, rather than qualitative alterations of the reticulin framework, was found to differ between adrenocortical carcinoma and adenomas.[83]

Reticulin Algorithm

Altered reticulin framework in association with one of the following parameters:

- Vascular invasion
- Necrosis
- Mitoses exceeding 5 per 50 high-power fields

The Helsinki score was proposed in 2015 for predicting metastasis in adrenocortical carcinomas. Adrenocortical neoplasms from 177 adults with 5 years of follow-up were evaluated with the Weiss score, Weiss revisited score, and proliferation index by computer-assisted image analysis.[84] A weighted calculation of three parameters (mitotic activity, necrosis, and Ki67-labeling index) had 100% sensitivity and 99.4% specificity for diagnosing metastatic adrenocortical carcinoma, with a cutoff of 8.5. In a validation study the following year of 225 adrenocortical carcinomas, the Helsinki and Weiss scores were found to be predictive of poor prognosis.[85] Reports suggest that the Helsinki scoring system may be helpful in the evaluation of myxoid and oncocytic adrenocortical tumors.[85,86]

Helsinki Scoring System*

- Mitoses >5 per 50 high-power fields: score 3
- Necrosis: score 5
- Ki67 labeling index in hot spots

*Malignant: score ≥8.5

Myxoid adrenocortical neoplasms are uncommon, with most cases published as small series or case reports. These tumors are often functional. In a study from Mayo Clinic of 14 cases of adrenocortical neoplasms with a myxoid component comprising 10% to 95% of the tumor, all six characterized as adenomas were associated with benign behavior, while four of the eight carcinomas were associated with a fatal outcome, with two alive with disease and one alive without

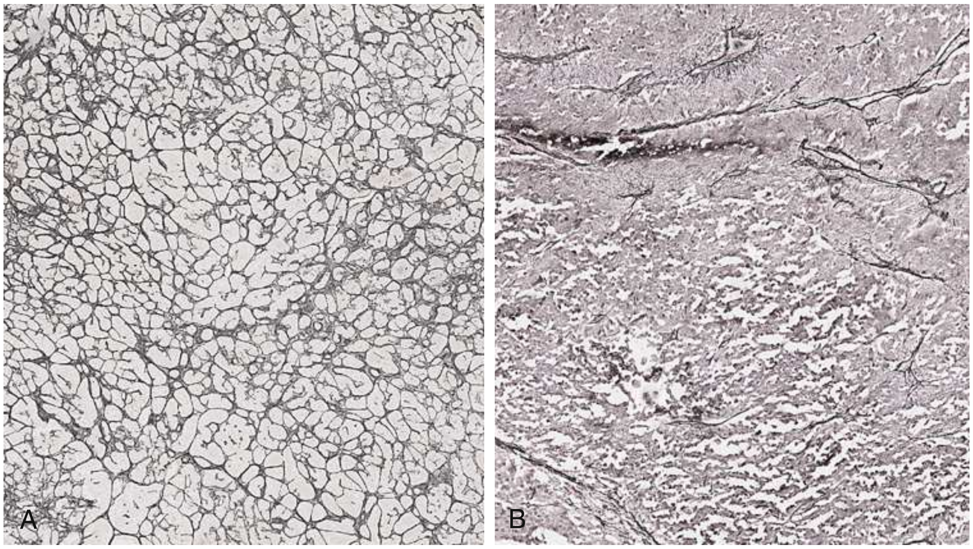

Fig. 91.26 Reticulin histochemistry in adrenocortical tumors. Adrenocortical adenomas are associated with retained acinar reticulin framework (**A**), whereas most adrenocortical carcinomas show loss of reticulin framework (**B**). The latter forms the basis of the reticulin algorithm. However, the identification of altered reticulin framework is often coupled with one of the three criteria proposed on this algorithm.

disease.[87] The immunohistochemical findings are similar to other adrenocortical neoplasms. A subsequent study from Italy by Papotti et al. evaluated four conventional adrenocortical carcinomas with focal myxoid change (5%–20% of the tumor), and found one of the four patients died of disease, and three were alive without disease at the end of the study.[71] They also evaluated 10 myxoid adrenocortical carcinomas with small cells, mild atypia, cords, and microcysts, and six of the 10 died of disease, one was alive with disease, and three were alive with no disease at follow-up. The most striking part of this study is that one of the two tumors with a Weiss score of 1 had a fatal outcome. Thus, the behavior of myxoid adrenocortical tumors is difficult to predict with standard morphological criteria. However, myxoid change does not make an adrenocortical neoplasm as malignant, but the behavior is difficult to predict with standard diagnostic systems.

Oncocytic adrenocortical tumors may be overdiagnosed as malignant by applying the standard Weiss systems. In 1998 Lin et al. evaluated seven oncocytic adrenocortical tumors (5–13.5 cm), all showing nuclear atypia and increased Ki67 proliferative index, but none had invasion or metastasis, and all behaved in a benign manner.[73] In 2004, Bisceglia and colleagues evaluated 10 oncocytic adrenocortical tumors and found that two criteria (clear cells less than or equal to 25% of the tumor and high nuclear grade) were present in all of the oncocytic tumors studied, and diffuse architecture was present in nine of 10.[72] They proposed an algorithm including the remaining six Weiss parameters and an additional criterion of "large size and huge weight" (greater than 10 cm and/or greater than 200 g). The current system used to evaluate oncocytic adrenocortical carcinoma is referred to as the "Lin–Weiss–Bisceglia system," which is comprised of major criteria and minor criteria. The presence of one or more major criteria (high mitotic rate, atypical mitoses, or vascular invasion) is diagnostic of malignancy. One to four minor criteria (large size and huge weight, necrosis, capsular invasion, or sinusoidal invasion) indicates a tumor of uncertain malignant potential. Tumors with no major or minor criteria are regarded as benign.[72] In 2011, a subsequent study of 13 oncocytic adrenocortical neoplasms and all published oncocytic adrenocortical neoplasms confirm the Lin–Weiss–Bisceglia system.[88] They also found that 30% of these tumors were functional, and these tumors are associated with median survival of 58 months (which is comparatively longer than for conventional adrenocortical carcinomas). A recent multicenter retrospective study from France matching oncocytic adrenocortical tumors with conventional adrenocortical carcinomas for age, sex, European Network for the Study of Adrenal Tumors (ENSAT) stage, and resection status also showed oncocytic adrenocortical carcinomas to be associated with better overall survival than conventional adrenocortical carcinomas.[86] Similar to all adrenocortical neoplasms, extensive sampling of oncocytic adrenocortical neoplasms is required so that the correct criteria are utilized, as the behavior does vary with the amount of oncocytic change. What is regarded as a pure oncocytic tumor requires greater than 90% of the tumor be oncocytic, requiring extensive sampling of an adrenocortical neoplasm. Mixed oncocytic adrenocortical tumors are characterized as clear cell component of 10% to 50% of cells, and in an adrenocortical tumor with focal oncocytic change the oncocytic component comprises less than 50% of the tumor.[27]

Lin–Weiss–Bisceglia Criteria for Oncocytic Adrenocortical Tumors*

Major Criteria:

- Mitoses >5 per 50 high-power fields
- Atypical mitoses
- Vascular invasion

Minor Criteria:

- Large tumor size (>10 cm) and weight >200 g
- Capsular invasion
- Necrosis
- Sinusoidal invasion

Malignant: at least one major criterion
Uncertain malignant potential: at least one minor criterion
Benign: absence of major and minor criteria

Sarcomatoid adrenocortical carcinomas are extremely rare and highly aggressive tumors that occur over a wide age range and are generally nonfunctioning.[89] Sarcomatoid adrenocortical carcinomas may have a component of more conventional adrenocortical carcinoma or can be completely sarcomatoid in appearance. These tumors must be differentiated from retroperitoneal sarcomas. Most sarcomatoid adrenocortical carcinomas exist in the literature as case reports. A study of six cases, three of which had been previously reported, evaluated the pathologic and immunohistochemical features of these tumors and had targeted next-generation sequencing analysis performed.[89] Among the six sarcomatoid adrenocortical carcinomas, the authors identified 16 morphologically distinct tumor components, eight of which were epithelial, and eight of which were sarcomatoid.[89] Thus, the morphologic heterogeneity of these tumors is quite remarkable and may account for some of the difficulty in differentiating these tumors from retroperitoneal sarcoma or other tumors. In the series above, patients ranged in age from 23 to 79 years, with a mean age of approximately 54 years. The tumors were large in size, averaging 14 cm (range: 6.5–24 cm). Some of the tumors had spindle cell components, with some having foci of osteosarcomatous differentiation, rhabdomyosarcomatous differentiation, or even PNET-like areas. Purely mesenchymal components such as osteosarcomatous or rhabdomyosarcomatous were less common. Keratin (AE1/AE3) showed focal positivity in the epithelial component of one tumor and in the sarcomatoid components of two tumors, but was otherwise negative. SF1 was present in epithelial component of all cases but negative in the sarcomatoid areas. Interestingly, β-catenin showed aberrant nuclear staining in the sarcomatoid component of five of the six cases. They also found *TP53* and *CTNNB1* mutations in both epithelial and sarcomatoid components, which they note supports a common clonal origin in at least a subset of these tumors.[89]

Wieneke Criteria for Pediatric Adrenocortical Tumors*

1. Tumor weight >400 g
2. Tumor size >10.5 cm
3. Mitoses >15 per 20 high-power fields
4. Atypical mitotic figures
5. Vena cava invasion
6. Capsular invasion
7. Vascular invasion
8. Extension into adrenal soft tissue or adjacent organs
9. Necrosis

Malignant/poor outcome: *score ≥4*
Uncertain malignant potential: *score 3*
Benign behavior: *score ≤2*

Pediatric adrenocortical neoplasms are not evaluated with the same classification systems as adult adrenocortical neoplasms. Pediatric tumors may have features that in an adult adrenocortical tumor would be very worrisome for malignancy. Thus, the Wieneke system is often utilized for these challenging tumors.[74]

DIAGNOSTIC AND PREDICTIVE IMMUNOHISTOCHEMICAL BIOMARKERS IN ADRENAL PATHOLOGY

Confirmation of Adrenocortical and Medullary Origin

KEY POINTS

- Biomarkers are frequently used in the distinction of nonfunctional adrenocortical neoplasms from other tumors. As adrenocortical carcinoma is an exceptionally rare tumor, a frankly malignant neoplasm in the adrenal gland would more likely be a metastasis from another site than a primary adrenocortical carcinoma. Immunohistochemical studies to characterize the tumor as a primary adrenocortical tumor are critical.

Adrenocortical neoplasms will often show variable staining for keratins; however, significant staining for keratin is not always identified, rather it is often focal and weak. SF1 is the most reliable biomarker that should be used to confirm the adrenocortical origin[31,90] (Fig. 91.27). However, several other somewhat less specific immunohistochemical stains (melan-A, synaptophysin, alpha-inhibin, and calretinin) are often used in traditional practices.[91,92] Nevertheless, one should recognize that synaptophysin[31] and alpha-inhibin[93] can be expressed in pheochromocytomas.

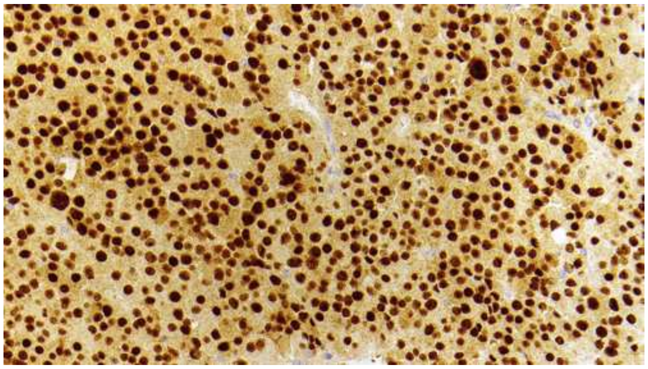

Fig. 91.27 **Confirmation of the adrenocortical origin.** Steroidogenic factor 1 is the most reliable biomarker that should be used to confirm the adrenocortical origin.

Pheochromocytomas are often positive for neuroendocrine differentiation markers (e.g., chromogranin-A, synaptophysin, and INSM1) and negative for keratins. When the distinction from other neuroendocrine neoplasms is indicated, the application of tyrosine hydroxylase (rate-limiting enzyme in catecholamine biosynthesis) or dopamine β-hydroxylase, along with GATA3 (variable), helps diagnosticians confirm the diagnosis of pheochromocytoma.[94-96] Most pheochromocytomas also show variable amounts of intratumoral sustentacular cells that are typically positive for SOX10 and S100. Evidence also suggests that sustentacular cells are not neoplastic in these tumors.[97] This may be helpful in distinguishing multifocal primary paragangliomas from metastasis in some anatomic sites such as liver and lung, where both primary and metastatic disease can occur.

Confirmation of Functional Sites in Primary Aldosteronism

Commercially available antibodies against steroidogenic enzymes have gained interest in the workup of functional sites in adrenalectomy specimens. The use of CYP11B2 immunohistochemistry adds great value to the workup of adrenalectomy specimens with primary aldosteronism.[31,34] Although assessment for this biomarker is generally not routinely performed in pathology laboratories, the use of this biomarker may be especially useful when dealing with multiple adrenal nodules or when no nodules are noted in the gross examination.

Diagnostic and Predictive Biomarkers of Adrenocortical Carcinoma

Numerous biomarkers have been evaluated diagnostically and prognostically in adrenal pathology.[31,83] Proliferation markers such as Ki67 (MIB1), proteins (IGF2, CDKN1C/p57, H19) associated with genes on chromosome 11p15 (which is also involved in Beckwith–Wiedemann syndrome); p53, for which *TP53* (17q13) mutations occur in Li–Fraumeni syndrome, and somatic *TP53* mutations and allelic loss of 17p13 may be seen in sporadic adrenocortical carcinomas; and alterations involving the Wnt/β-catenin-signaling pathway, among others.[9,29,31,83]

Advances in our understanding of the molecular pathogenesis of adrenocortical carcinoma underscored the importance of p53 and β-catenin as prognostic biomarkers, because most carcinomas with adverse molecular clusters tend to display nuclear β-catenin expression and/or abnormal p53 staining (overexpression or global loss) (Fig. 91.28). For this reason, endocrine pathologists are increasingly using

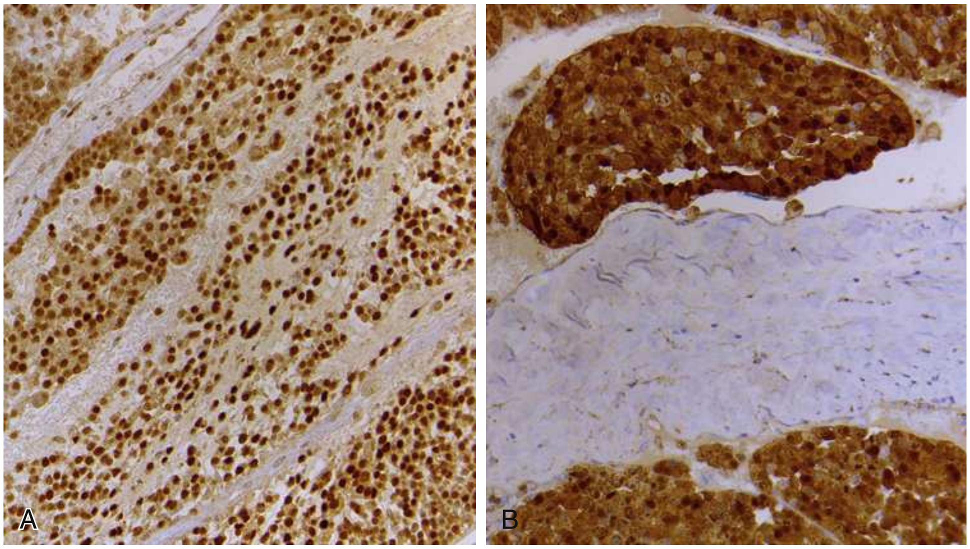

Fig. 91.28 **p53 overexpression and nuclear β-catenin expression.** p53 overexpression is seen in a subset of adrenocortical carcinomas that are often associated with high-grade proliferative disease (**A**). Diffuse nuclear β-catenin is also seen in some adrenocortical carcinomas, particularly in adverse molecular clusters (**B**).

both p53 and β-catenin immunohistochemistry in the workup of adrenocortical carcinomas.[27,29,31,83]

KEY POINTS

- IGF2 immunohistochemistry stands out as an important diagnostic biomarker of adrenocortical carcinomas.

Mete et al. demonstrated IGF2 immunohistochemistry optimized to detect paranuclear dot-like reactivity in adrenocortical carcinomas in adults[83] (Fig. 91.29).

Proliferative activity in adrenocortical neoplasms is a continually important theme. The mitotic rate is present in numerous diagnostic algorithms and is considered by some as the most important criterion of malignancy.[98] Proliferative activity as measured with a Ki67 labeling index of greater than 5% has been suggested as a sensitive and specific marker for malignancy[83,99,100] (Fig. 91.30). A combination of Ki67 proliferative index and IGF2 expression has also been proposed to be useful in separating adrenocortical carcinomas from adenomas.[83,100,101] The widely adopted Ki67 prognostic groups of less than 10%, 10% to 19%, and greater than 20% are also suggested by the WHO classification.[69] Given the critical value of Ki67 labeling index, eyeballing is less accurate. The use of pathologist-driven automated image analysis nuclear algorithms or manual counting is helpful to more reliably determine the Ki67 proliferation index that can also be reproduced by other users[27,106,107] (Fig. 91.31).

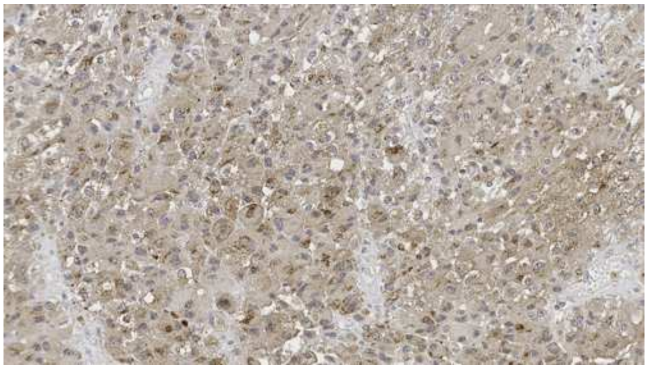

Fig. 91.29 IGF2 immunohistochemistry in the distinction of adrenocortical carcinoma. Irrespective of tumor cytomorphology, proliferative grade, or functional status of the tumor, paranuclear IGF2 reactivity is a reliable diagnostic biomarker of adrenocortical carcinoma.

KEY POINTS

- Mitotic rate and proliferative activity as measured by Ki67 have been used in the grading and prognosis of adrenocortical carcinomas over time.[81,83,102-105]

SF1 immunohistochemistry not only confirms the cortical origin of an adrenal mass, but may also have prognostic impact.[31,90] It has been reported that high expression of SF1 (N1665 antibody) positively correlated with high mitotic count, high Ki67 index, high stage, and decreased survival in a study of 75 adrenocortical carcinomas that also included myxoid in oncocytic variants.[90]

Immunohistochemistry for MMR proteins (MLH1, MSH2, MSH6, and PMS2) has been frequently used by endocrine pathologists,[31] as adrenocortical carcinoma is one of the extracolonic manifestations of Lynch syndrome[108,109] and may help determine eligibility for treatment options in affected patients.

Molecular Immunohistochemistry in Pheochromocytoma

In the evaluation of pheochromocytomas and paragangliomas, there are several biomarkers that can help predict disease pathogenesis and germline susceptibility. Commercially available antibodies against SDHB have revolutionized the screening process for more than a decade in endocrine pathology practice.[110] Given the genotype–phenotype correlations, pheochromocytomas lacking a mature secretory phenotype (absence of adrenergic secretion) is usually assessed for SDHB immunohistochemistry.[51] Germline DNA from patients with SDH-deficient tumors should be screened for all *SDHx* (*SDHA*, *SDHB*, *SDHC*, *SDHD*, and *SDHF2*) pathogenic variants, because a small fraction of SDH-deficient tumors may also be related to somatic/epigenetic alterations.[111] Antibodies against SDHA (e.g., loss of SDHA expression suggests SDHA-related pathogenesis) have also shown promise and are being used in clinical practice.[110,111]

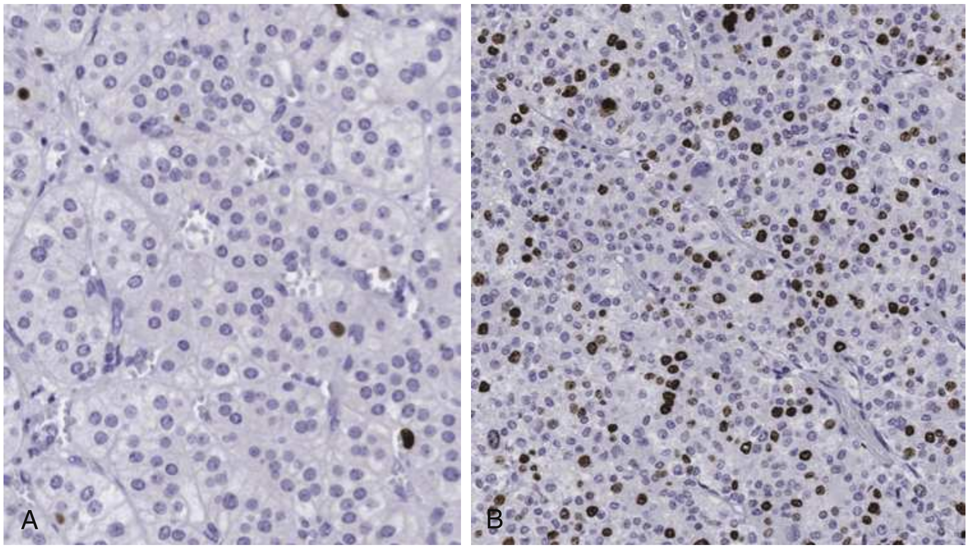

Fig. 91.30 Ki67 proliferation index in the distinction of adrenocortical carcinoma. Most adrenocortical adenomas have a Ki67 labeling index of less than 5% (**A**), whereas adrenocortical carcinomas tend to show higher labeling indices (**B**).

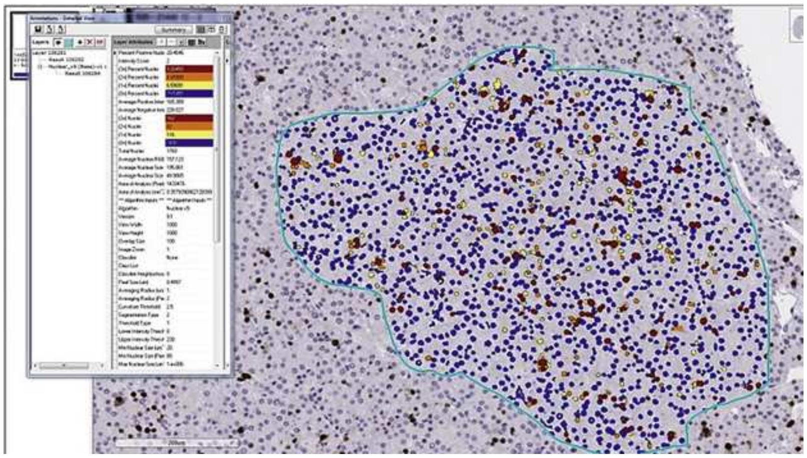

Fig. 91.31 Manual or automated counting of Ki67 labeling index. The current standard of practices requires meticulous assessment of the Ki67 labeling index in adrenocortical carcinomas. Eyeballing is no longer recommended. This photomicrograph illustrates a pathologist-driven automated image analysis nuclear algorithm in a patient with adrenocortical carcinoma.

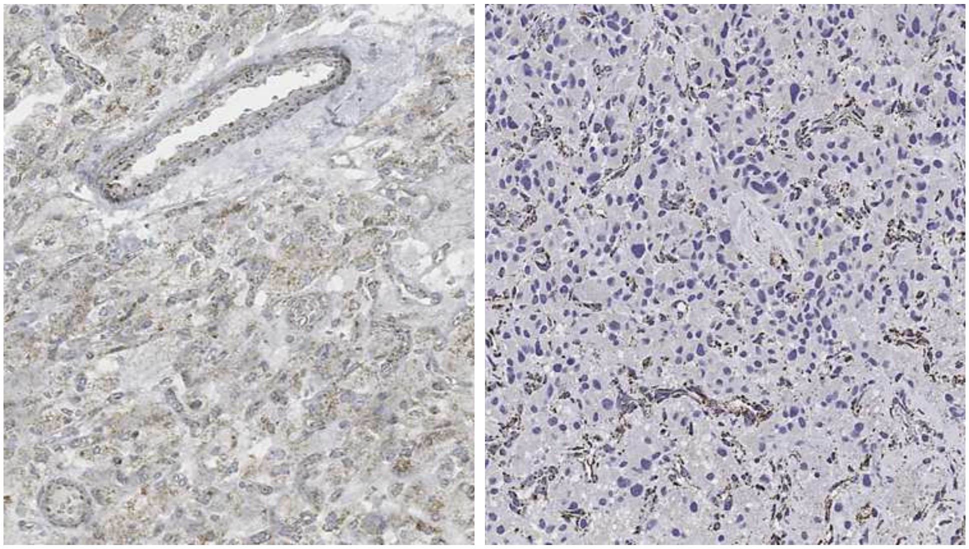

Fig. 91.32 SDHB immunohistochemistry in pheochromocytoma. This composite photomicrograph illustrates two pheochromocytomas. The tumor on the left shows normal SDHB expression, which argues against *SDHx*-related pathogenesis. The tumor on the right tumor displays loss of cytoplasmic granular SDHB expression in the tumor, while the nontumorous endothelial cells still display preserved granular reactivity. This finding is consistent with a SDH-deficient pheochromocytoma and requires germline testing of all *SDH* genes.

KEY POINTS

- The term SDH-deficient pheochromocytoma is applied to a pheochromocytoma that shows loss of cytoplasmic granular SDHB reactivity, while nontumorous elements preserve SDHB reactivity (Fig. 91.32).

KEY POINTS

- SDHB immunohistochemistry is also of clinical significance during the interpretation of *SDHx* variants of uncertain significance (VUS), because loss of SDHB expression by immunohistochemistry would favor a pathogenic process in the setting of VUS.[51]

Other molecular immunohistochemistry tools available to pathologists include antibodies against MAX and FH/2-SC that correlates with *MAX*- and *FH*-related pathogenesis.[112,113] *VHL*-related tumors often show membranous carbonic anhydrase IX staining[93,114,115] (Fig. 91.21). Recently, alpha-inhibin immunohistochemistry has been shown to predict pseudohypoxia-driven pathogenesis, including *SDHx*- and *VHL*-related pheochromocytomas[93] (Fig. 91.33).

SYNOPTIC REPORTING IN ADRENOCORTICAL CARCINOMA AND PHEOCHROMOCYTOMA

The synoptic templates of the College of American Pathologists and International Collaboration on Cancer Reporting (ICCR)

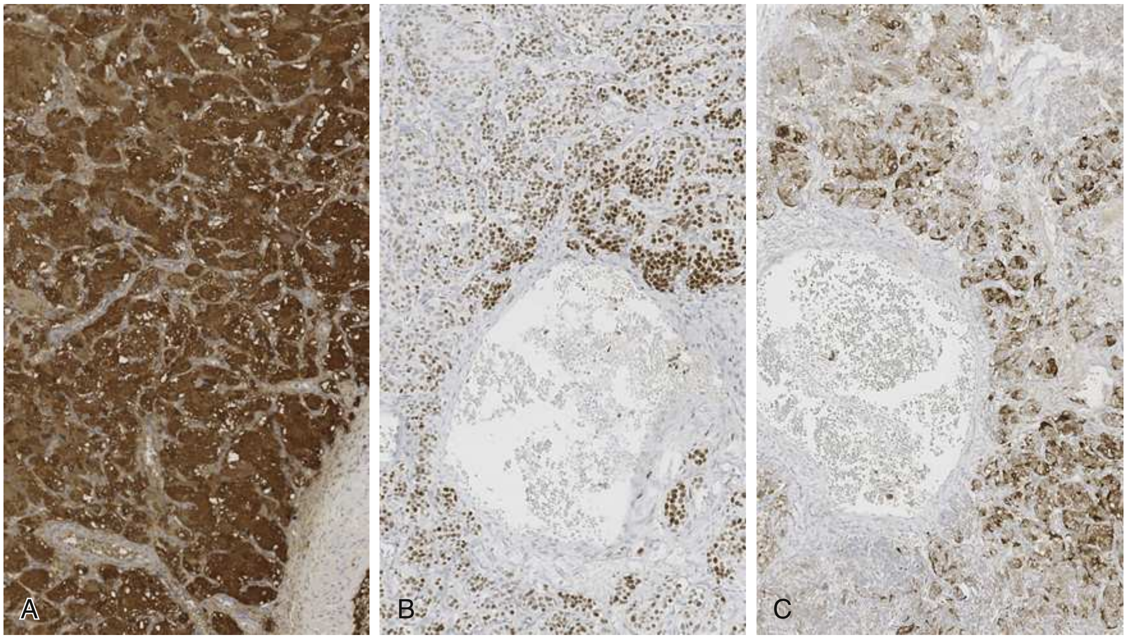

Fig. 91.33 **Alpha-inhibin expands biomarkers of pseudohypoxia-driven pathogenesis.** This composite photomicrograph illustrates a case of SDH-deficient pheochromocytoma. By immunohistochemistry, the tumor is positive for tyrosine hydroxylase (**A**) and GATA3 (**B**), confirming the diagnosis. SDHB immunohistochemistry is not illustrated. This tumor is also variably positive for alpha-inhibin (**C**). It is important to recognize this pitfall, as inhibin expression has been regarded as a marker of adrenal cortex, but recent evidence clearly confirms that this marker cannot be used in this distinction.

have been available for unified reporting of adrenocortical carcinomas.[107,116] The synoptic reports often integrate the pathological tumor-node-metastasis (TNM) data at the time of diagnosis.

European Network for the Study of Adrenal Tumors (ENSAT)

Stage I: Tumor confined to adrenal gland and <5 cm in diameter
Stage II: Tumor confined to adrenal gland and >5 cm in diameter
Stage III: Tumor involves surrounding tissue (not confined to the adrenal gland) or involvement of regional lymph node(s) or regional veins
Stage IV: Distant metastases

KEY POINTS

- Essential parameters that are reported in pheochromocytomas include (i) tumor size, (ii) presence/absence of extraadrenal invasion, (iii) presence/absence of composite elements, (iv) vascular invasion, (v) lymphatic invasion, (vi) mitotic activity (mitoses per 2 mm^2 based on 10 mm^2 from hot spots), (vii) tumor necrosis, (viii) status of resection margins, (ix) status of adrenal medullary hyperplasia, (x) Ki67 proliferation index, (xi) histologically confirmed nodal metastasis, and (xii) molecular immunohistochemistry (at least SDHB immunohistochemistry in all tumors with no mature secretory phenotype). It is desirable to integrate the findings on biochemical and functional imaging studies into a pathological report.

Until the eight edition of the American Joint Committee on Cancer (AJCC) TNM staging system, there was no formal TNM staging for pheochromocytomas. The current AJCC TNM staging introduced three distinct pT stages based on size (the cut-off of 5 cm) and presence of extra-adrenal invasion into surrounding tissues (see https://www.facs.org/quality-programs/cancer/ajcc for AJCC staging information). Because pheochromocytomas/paragangliomas are neuroendocrine neoplasms with metastatic potential, these tumors are now staged and are required to be reported using synoptic templates that are available to pathologists. The very first multidisciplinary international expert consensus synoptic template for pheochromocytomas and paragangliomas was introduced back in 2014[110]; and this was followed by additional reporting guides including but not limited to the ICCR template.[117]

KEY POINTS

- In adrenalectomy specimens, essential histological parameters that should be covered in adrenocortical carcinomas include (i) tumor size, (ii) presence of extraadrenal invasion, (iii) gross invasion into a large vein, (iv) microscopic vascular invasion, (v) microscopic lymphatic invasion, (vi) mitotic activity, reported as per number of mitoses per 50 high-power fields, (vii) atypical mitoses, (viii)tumor mitotic grade (low or high grade, based on the cutoff of 20 per 50 high-power fields), (ix) tumor necrosis, (x) Ki67 proliferation index, (xi) status of resection margins, and (xii) status of nodal disease (if lymph nodes are excised).

INTRODUCTION

A variety of different pathologies can affect the adrenal glands. High-resolution anatomic imaging with computed tomography (CT) and magnetic resonance imaging (MRI) can demonstrate subtle irregularities of the adrenal contours and can identify lesions millimeters in size. When combined with sensitive biochemical tests of adrenocortical and medullary hormones, diagnosis of adrenal gland dysfunction can be made at very early stages of disease. Certain adrenal pathologies can be confidently diagnosed based on imaging features alone and can potentially circumvent the need for percutaneous tissue sampling. Additionally, functional imaging with nuclear medicine scintigraphy and positron emission tomography (PET) add significant clinical utility, particularly in the evaluation of biochemically functional tumors as well as distant extra-adrenal metastatic disease.

ADRENAL GLAND ANATOMY

The adrenal glands are located in the retroperitoneum in the superior aspect of Gerota's fascia in the perirenal space. These paired glands typically lie adjacent and lateral to the first lumbar vertebral body. The adrenal glands are suprarenal structures with the right gland lying more cranial relative to the left. They demonstrate an inverted-Y or inverted-V morphology with posteromedial and posterolateral limbs. The left gland tends to be slightly larger, with a width measuring up to 8 mm, whereas the width of the right gland measures up to approximately 6 mm (Fig 92.1).[1]

Histologically, there are two distinct components of the adrenal glands, an outer cortex and an inner medulla, which together can have a trilaminar appearance, although this is often not well depicted on imaging. The cortex is further subdivided into three zones, each with its own dedicated function: the zona glomerulosa, the zona fasciculata, and the zona reticularis. The zona glomerulosa is the outer most component of the cortex, secretes aldosterone, and is involved with electrolyte balance. The zona fasciculata, located just deep to the zona glomerulosa, synthesizes glucocorticoids and is involved with glucose metabolism. Lastly, the zona reticularis, the innermost component of the cortex, is involved with sex hormone production. The medulla is involved in the production of catecholamines, epinephrine, and norepinephrine, and regulates the stress response. The adrenal gland is surrounded by a collagenous capsule that is not seen on cross-sectional imaging.

The arterial supply to each adrenal gland comes from three sources: a superior adrenal artery arising from the inferior phrenic artery, the middle adrenal from the aorta, and the inferior adrenal from the renal artery. One or more central veins drain the cortex and the medulla and form the adrenal vein. The adrenal vein often freely communicates with one or more retroperitoneal and/or hepatic veins. The right adrenal vein is shorter than the left and usually enters the right posterolateral surface of the inferior vena cava (IVC) at a level between the eleventh and twelfth ribs. The central vein of the left adrenal gland joins the left inferior phrenic vein to form the phrenicoadrenal trunk, which then enters the superior aspect of the left renal vein. Collateral communications with renal capsular, azygous, and retroperitoneal veins are common. These descriptions are of classic venous anatomy and there are numerous described anatomic variants.

KEY POINTS

- The adrenal gland is made of a cortex and medulla, each having specific endocrine function and related pathology.

ADRENAL GLAND IMAGING

Ultrasound, while it is widely available and does not involve ionizing radiation, has limited diagnostic utility in the evaluation of the adrenal glands in adult patients due to size and location. It is, however, the imaging modality of choice for adrenal gland

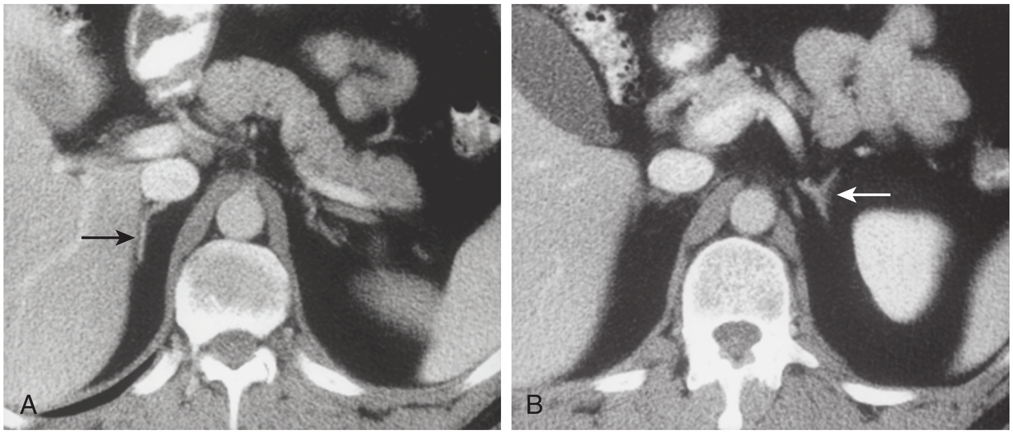

Fig. 92.1 Computed tomography appearance of normal adrenal glands. **A,** The cephalad portion of the right adrenal *(arrow)* is seen. **B,** The three limbs of the left adrenal *(arrow)* are shown at this level. (From Korobkin M, Francis IR. Adrenal imaging. *Semin Ultrasound CT MR.* 1995;16:317–330.)

evaluation in the pediatric population and is particularly useful for the assessment of adrenal hemorrhage and masses such as neuroblastoma (NB). The adrenal glands are normally hypoechoic or have echogenicity that is similar to that of adjacent perirenal fat. A hyperechoic center can sometimes be seen, corresponding with the medulla. Ultrasound may also have a role in percutaneous image-guided biopsies of adrenal masses in both pediatric and adult patients.

CT is currently the primary method of anatomic imaging of the adrenal gland and can visualize the glands in virtually all cases. The attenuation and enhancement of the adrenal glands are similar to soft tissue. Adrenal abnormalities are often identified incidentally (e.g., "incidentaloma") during evaluation of a separate indication other than adrenal mass detection. Density measurements can be helpful for lesion analysis. A dedicated adrenal protocol CT can be especially beneficial for further characterization, particularly in distinguishing between a benign adenoma from metastatic disease.

MRI, in comparison with CT, demonstrates improved tissue contrast and utility in patients with renal insufficiency or iodinated contrast allergy. On MRI, the adrenal glands are isointense to the spleen on T1-weighted sequences and iso- to hypointense to the spleen on T2-weighted sequences. Fat-saturation sequences to detect macroscopic fat and in- and out-of-phase sequences to detect intracellular lipid provide additional utility for lesion characterization. Recent advances in MRI technology have made MRI a competitive method with CT for imaging suspected adrenal disease.

Positron emission tomography (PET)/CT using (^{18}F)-fluorodeoxyglucose (FDG) is now widely used for imaging of hematological and solid malignancies that have characteristic overexpression of insulin-independent glucose transporters (GLUT1, GLUT3) leading to uptake and intracellular trapping of FDG in cancer cells. FDG-PET/CT allows characterization of the "molecular signature" of an adrenal mass and can identify adrenal metastases with excellent sensitivity and high specificity.[2,3]

Radiopharmaceuticals for adrenocortical imaging have been available for more than 30 years, since the mid 1970s, with the radiocholesterol analog ^{131}I-6β-iodomethylnorcholesterol (NP-59) being the first in commercial use[4] and newer radiopharmaceutical inhibitors of 11β-hydroxylase, ^{11}C-etomidate and ^{11}C-, ^{18}F-, and ^{123}I-metomidate developed for imaging the normal adrenal cortex and various adrenocortical tumors.[5] The first clinically successful adrenal medulla imaging agent, metaiodobenzylguanidine (MIBG), labelled with ^{123}I or ^{131}I, was developed in the early 1980s and continues to be used clinically for imaging pheochromocytoma, paraganglioma, and NB.[6] MIBG accumulation in neuronal tissues involves the norepinephrine transporter reuptake mechanism, and subsequent packaging by the vesicular monoamine transporter into catecholamine storage vesicles of adrenergic nerves and adrenomedullary cells. Other PET radiotracers for adrenomedullary imaging of pheochromocytoma are being investigated, including ^{18}F-6-fluorodopamine (18F-DA), ^{18}F-fluorodihydroxyphenylalanine (18F-DOPA), and ^{11}C-hydroxyephedrine (HED).[7-9]

^{68}Ga-1,4,7,10–tetraazacyclododecane–1,4,7,10–tetraacetic acid (DOTA)–labeled somatostatin analogs have been developed for PET imaging of neuroendocrine tumors (NETs), affording image acquisition within sixty minutes postinjection and higher spatial resolution than radiotracers labeled for single-photon emission computed tomography (SPECT), supplanting the ^{111}In-DTPA-octreotide scintiscan. ^{68}Ga-DOTA peptide PET has been used to depict pheochromocytoma and paraganglioma successfully.[10]

KEY POINTS

- Several modalities are used to image the adrenal glands based on anatomy or function, the most common of which is computed tomography.

Arteriography and Adrenal Vein Sampling

Arteriography is used only in a few selected adrenal lesions or in the case of extraadrenal pheochromocytoma, when additional information about tumor resectability and vascular anatomy is needed. Adrenal venous sampling (AVS) is performed in patients with proven primary hyperaldosteronism to distinguish hypersecretory unilateral adenoma from bilateral adrenal hyperplasia (Fig 92.2). Rarely, AVS is performed to determine whether autonomous hormone excess is unilateral or bilateral in Cushing syndrome. Indications, specificity, and sensitivity, as well as data interpretations and treatment recommendations based on AVS, are discussed in another chapter in this textbook.

The specific risk with adrenal arteriography is rupture of the adrenal arteries with contrast extravasation. Potential complications of adrenal vein catheterization include intraadrenal extravasation of contrast medium, bleeding, and adrenal vein thrombosis. Adrenal hemorrhage can cause severe pain and fever, as well as destruction of adrenal glandular function and hypoadrenalism if both adrenal glands are damaged.

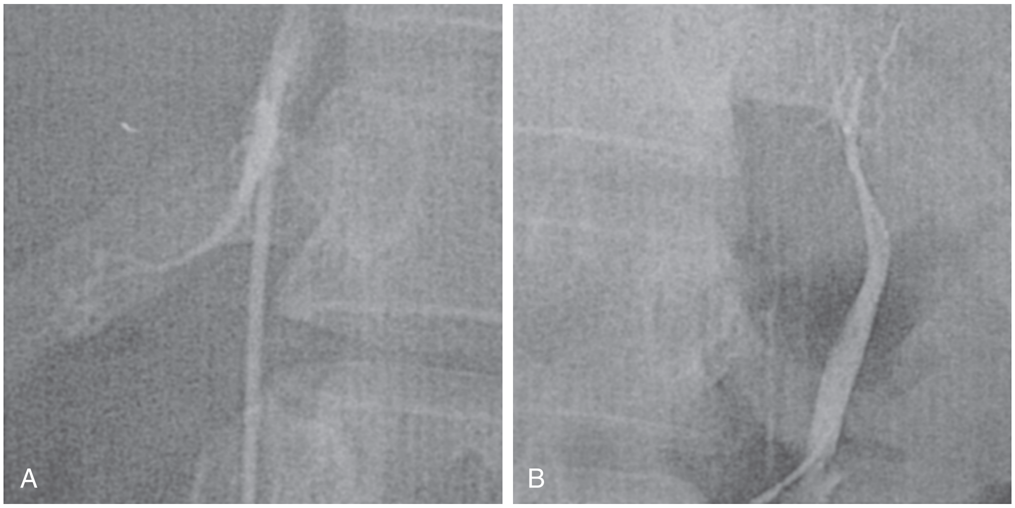

Fig. 92.2 Bilateral adrenal venograms in a patient with primary hyperaldosteronism. **A,** Right adrenal venogram in the left anterior oblique projection. The intrarenal branches are filled poorly. The main vein enters the posterolateral aspect of the inferior vena cava. **B,** Left adrenal venogram in the anteroposterior projection with the injection of contrast medium via the 3F microcatheter introduced through the 5F reverse hook catheter positioned near the junction of the main adrenal vein and the left renal vein.

KEY POINTS

- Adrenal vein sampling (AVS) allows direct measure of adrenal hormone synthesis.
- AVS is invasive and technically challenging.

CLINICAL UTILITY

Adenoma or Metastases

The increasing availability and use of anatomic imaging, particularly CT, performed for indications unrelated to the adrenal gland have led to a growing number of incidentally found adrenal lesions, also termed incidentalomas. The discovery of an adrenal mass presents a diagnostic and, at times, a therapeutic challenge. The evaluation of these incidentalomas could require identification of malignancy and would subsequently impact clinical management. The clinical history of a preexisting cancer diagnosis is important due to significant differences in prevalence of adrenal malignancy in oncologic versus nononcologic patients. In addition, it is necessary to distinguish if the adrenal mass is functional or hormonally active by biochemical testing of secretory function (screening for mineralocorticoid, glucocorticoid, and catecholamine secretion).

Because the overwhelming majority of incidentalomas are benign, an aggressive approach is often not indicated. The prevalence of adrenal adenomas is high, ranging from 4% to 10% of patients studied with CT or MRI for indications other than suspected adrenal disease.[11] Small, homogeneous adrenal masses discovered incidentally are likely to be adenomas. Unenhanced CT densitometry can be used to accurately differentiate adrenal adenomas from metastases. Most adenomas, which are lipid-rich, have unenhanced CT attenuation values lower than those of metastases. In a histologic/radiologic study of a small number of resected adrenal adenomas that had undergone presurgical unenhanced CT, chemical shift MRI, or both, a good inverse linear correlation was seen between the estimated number of lipid-rich cells and the unenhanced CT attenuation values, and a good linear correlation was noted with the relative change in signal intensity on opposed-phase MRI (Figs. 92.3 and 92.4).[12]

In the scenario of an oncologic patient with an unsuspected adrenal mass and no other evidence of metastatic disease, the goal of noninvasive diagnostic adrenal imaging is to identify an adrenal adenoma with high specificity, and thus exclude adrenal metastases. With the use of pooled data from multiple published studies, it has been shown that the most optimal combination of a sensitivity (71%) and specificity (98%) for the diagnosis of lipid-rich adrenal adenoma is achieved when a threshold attenuation value of <10 Hounsfield units (HU) is used on unenhanced CT (Fig. 92.5).[13] However, lipid-poor adenomas tend to have attenuation values greater than 10 HU on unenhanced CT imaging and are thus more difficult to distinguish from metastases. Additionally, postcontrast attenuation values for all adenomas, whether lipid-rich or lipid-poor, show considerable overlap with metastases. This poses a diagnostic dilemma on routine single-phase contrast-enhanced CTs of the abdomen and pelvis.

For indeterminate adrenal lesions (e.g., those with unenhanced attenuation values >10 HU or lesions identified on a routine contrast-enhanced CT), a dedicated adrenal protocol CT is beneficial for distinguishing between benign adenomas from metastases. Adrenal adenomas, whether lipid-rich or lipid-poor, demonstrate rapid washout of contrast. A dedicated adrenal protocol CT typically includes precontrast, 60 to 75-second postcontrast, and 15-minute delayed imaging. Absolute washout is calculated as follows: [(postcontrast HU – delayed HU)/(postcontrast HU – precontrast HU)] x 100. In cases where precontrast imaging is not obtained, a relative washout can be calculated as follows: [(postcontrast HU – delayed HU)/postcontrast HU)] x 100. Adenoma can be diagnosed with absolute washout greater than or equal to 60% or relative washout greater than or equal to 40% (Fig. 92.6). In a prospective study of 166 adrenal masses with unenhanced CT, those with attenuation values greater than 10 HU underwent contrast-enhanced and 15-minute delayed enhanced CT. This protocol correctly characterized 160 of the 166 masses (96%). Exclusion of primary adrenal neoplasms increased sensitivity and specificity for characterizing a mass as adenoma versus metastasis to 98% (124/127) and 97% (33/34), respectively.[14] Similar results were subsequently confirmed with similar protocols.[15,16] Therefore, a dedicated adrenal protocol CT to calculate washout is being used in many centers to characterize incidentally discovered adrenal masses.

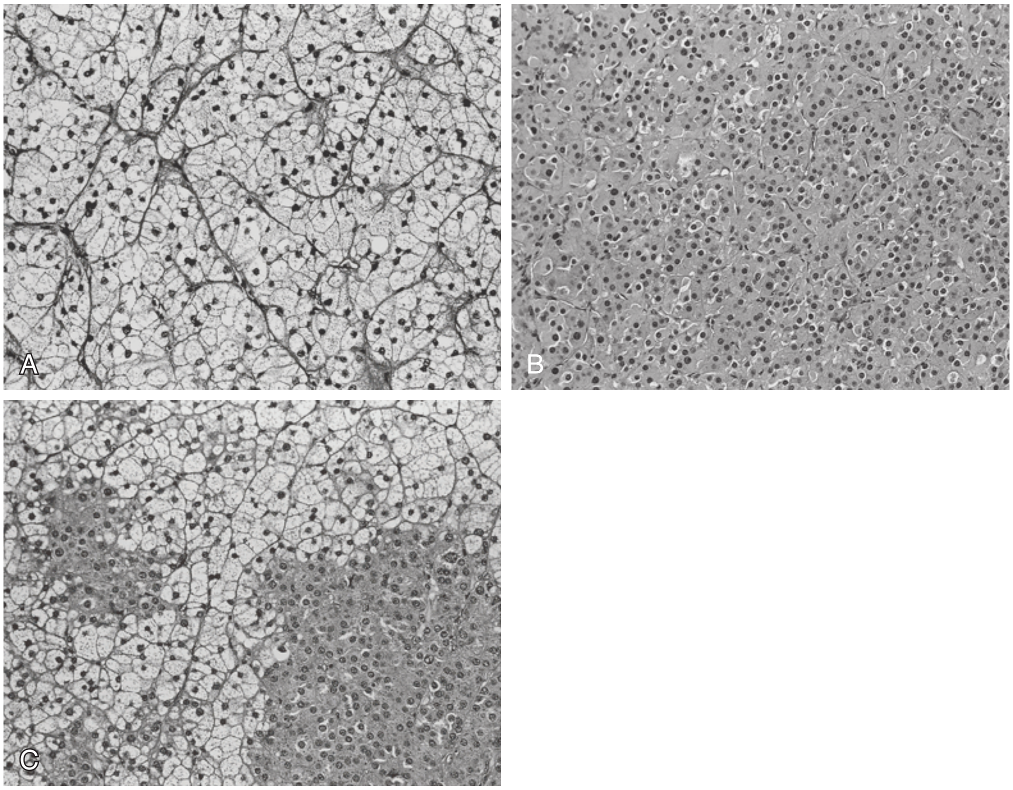

Fig. 92.3 **Histologic specimens from resected adrenal adenomas. A,** Primarily of lipid-rich clear cells. **B,** Primarily of lipid-poor clear cells. **C,** Of an admixture of clear and compact cortical cells. (Hematoxylin and eosin stain, original magnification ×200.) (From Korobkin M, Giordano TJ, Brodeur FJ, et al. Adrenal adenomas: relationship between histologic lipid and CT and MR findings. *Radiology*. 1996;200:743–747.)

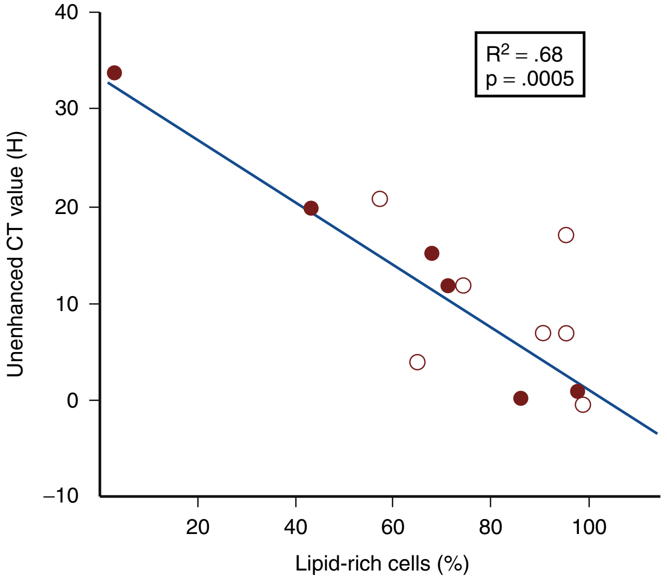

Fig. 92.4 **Plot of unenhanced computed tomography attenuation number versus the percentage of lipid-rich cells in 13 surgically resected adrenal adenomas.** *HU*, Hounsfield units. (From Korobkin M, Giordano TJ, Brodeur FJ, et al. Adrenal adenomas: Relationship between histologic lipid and CT and MR findings. *Radiology*. 1996;200:743–747.)

Notably, the assessment of enhancement washout curves for adrenal masses is valid only for lesions with relatively homogeneous attenuation after contrast enhancement; the diagnosis of adrenal adenoma cannot be made in masses that contain prominent regions of necrosis or hemorrhage.

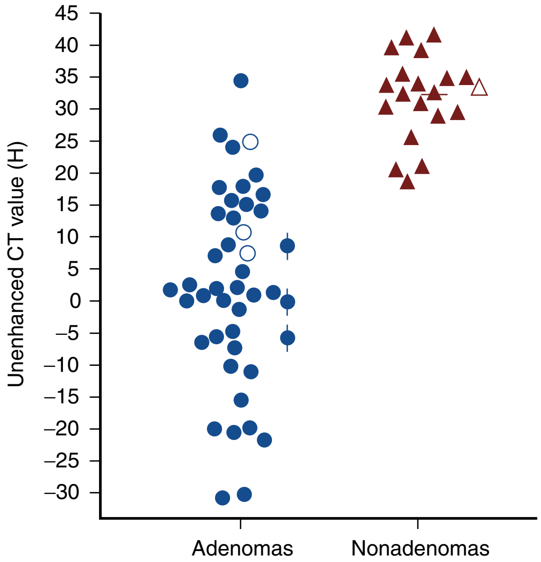

Fig. 92.5 **Scattergram of attenuation values on unenhanced compute tomography of adrenal adenomas and nonadenomas.** All masses with H values of less than 18 were adenomas. ●, Nonhyperfunctioning adenomas; O, Cushing adenomas; ●, primary aldosteronism adenomas; ▲, metastases; Δ, pheochromocytomas; ▲, cortical carcinomas. (From Korobkin M, Brodeur FJ, Yutzy GG, et al. Differentiation of adrenal adenomas from nonadenomas using CT attenuation values. *Am J Roentgenol*. 1996;166:531–536.)

On MRI, chemical shift sequences can be used to identify intracytoplasmic lipid and can therefore distinguish adenomas.[17,18] Taking advantage of the different precession rates for hydrogen atoms in water

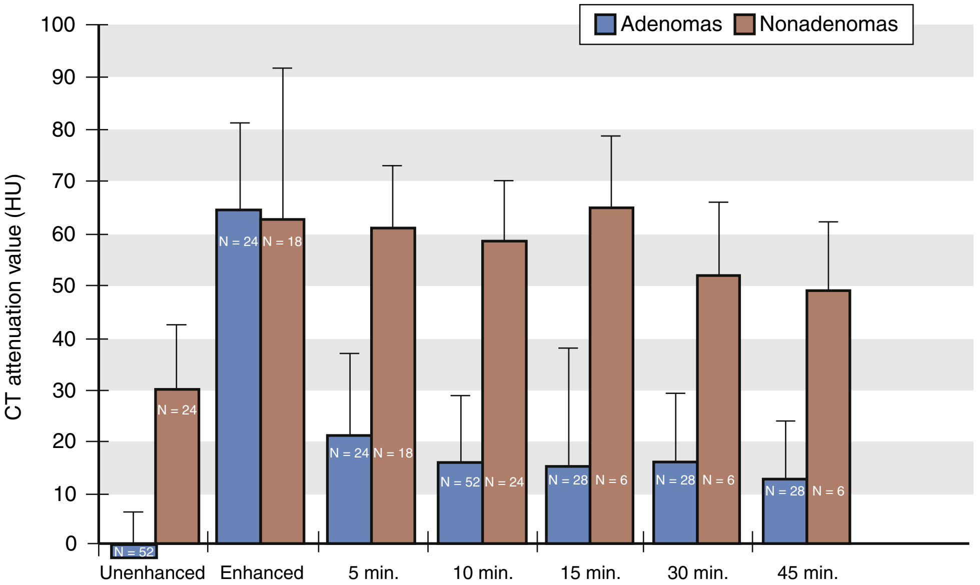

Fig. 92.6 Bar graph shows mean computed tomography attenuation value plus 1 standard deviation for adrenal adenomas *(black)* and nonadenomas *(white)* on unenhanced, enhanced, and delayed enhanced scans. (From Korobkin M, Brodeur FJ, Francis IR, et al. CT-time-attenuation washout curves of adrenal adenomas and nonadenomas. *Am J Roentgenol.* 1998;170:747–752.)

and lipid molecules, chemical shift MRI results in a decrease in signal intensity on opposed-phase versus in-phase imaging in tissue containing intracellular lipid that is often present in adenomas and absent in most metastases. Assessment of the chemical shift change can be made via simple visual analysis or by quantitative methods using standard region-of-interest measurements of the mass (Fig 92.7). The two most commonly used formulae for quantitative analysis of chemical shift change are the signal intensity index (SII) and adrenal-to-spleen chemical shift ratio (ASR). SII is calculated by $[(IPI_a - OPI_a)/IPI_a] \times 100$ and ASR is calculated by $[(OPI_a/OPI_s)/(IPI_a/IPI_s)] \times 100$, where IPI_a represents in-phase intensity in the adrenal, OPI_a represents opposed-phase intensity in the adrenal, IPI_s represents in-phase intensity in the spleen, and OPI_s represents opposed-phase intensity in the spleen. An SII of 16.5% (or 20%) and an ASR of less than 0.71 are considered to be highly accurate for the characterization of lipid-containing adrenal adenomas.[18-21]

The advent of FDG-PET/CT for determination of the metabolic signature of adrenal masses to predict malignant potential has replaced earlier work using functional adrenal imaging such as NP-59 or MIBG scintigraphy to characterize specific molecular processes of adrenal tumors.[22] A metaanalysis of 1217 patients from 21 studies reported that FDG-PET had a pooled sensitivity of 97% and specificity of 91% for distinguishing malignant from benign adrenal masses.[23] Another metaanalysis reported similar results, with pooled sensitivity 91% and specificity 91% for both FDG-PET and PET/CT, although significant heterogeneity of the included studies was noted.[24] In subjects without preexisting cancer history, FDG-PET/CT had sensitivity 86.7% and specificity 86.1% to distinguish malignant from benign etiology of adrenal incidentaloma.[25]

The accuracy of FDG-PET/CT appears to be similar using either qualitative or quantitative assessment of the adrenal mass uptake compared with adjacent liver background. In a recent study of metabolic parameters for characterization of adrenal incidentaloma in noncancer patients, a standardized uptake value (SUV) max cutoff greater than 3.1 and adrenal:liver ratio greater than 1.8 had 100% sensitivity and 67% specificity for identifying cancer.[26] Similar findings were reported in 59 patients (malignant lesions in 52 using histological gold standard), that adrenal tumor SUV threshold greater than 3.5 had an accuracy of 87% for predicting malignancy.[27] FDG-PET/CT metabolic measurements have been combined with CT histograms and unenhanced CT parameters (HU, size) on hybrid PET/CT cameras to improve diagnostic accuracy.[28,29]

Current evidence suggests a complementary role for FDG-PET/CT to CT for the assessment of indeterminate adrenal masses characterized by CT or MRI. In a systematic review of 353 indeterminate adrenal lesions measuring greater than 10 HU, CT showed a sensitivity 100% with a specificity of 33%, while 89 patients with FDG-PET/CT having a tumor:liver ratio greater than 1.8 had a sensitivity of 87% and a specificity 84% for malignancy. Therefore, FDG-PET is helpful in further characterization of indeterminate lesions, improving specificity.[30]

Despite excellent sensitivity, FDG-PET/CT false negatives can occur with small tumors (<5 mm), hemorrhagic or necrotic tumors, and tumors with low FDG avidity postchemotherapy.[31] Adrenal metastases secondary to pulmonary carcinoid or bronchioloalveolar lung carcinoma have produced false-negative PET results due to low FDG avidity in these cancers. False positives are reported in inflammatory/infectious processes, benign pheochromocytoma, adrenocortical adenoma, adrenal nodular cortical hyperplasia, myelolipoma, hemorrhagic nodules, adrenal endothelial cysts, and perirenal brown fat and following chemotherapy.[32] A case of a false-positive FDG-PET due to adrenal angiomyolipoma with a SUV of 18.8 was attributed to the effect of colony-stimulating factor on the tumor's hemopoietic components.[33] Interestingly, FDG-PET has been shown to allow metabolic assessment of response to mammalian target of rapamycin (mTOR) therapy in another case of adrenal angiomyolipoma.[34] Inflammation during immunotherapy due to ipilimumab-induced adrenalitis was reported to have uptake on PET.[35] Benign bilateral adrenal FDG uptake can occur with Cushing syndrome due to ectopic adrenocorticotropic hormone (ACTH),[36] and with ACTH-secreting esthesioneuroblastoma.[37] Bilateral adrenal FDG uptake has also been described with a vasovagal stress reaction.[38,39] The coexistence of an adrenal adenoma and a metastasis (collision adrenal tumor) has led to the apparently increased FDG activity in a benign-appearing lesion; careful coregistration of PET and CT data, as well as meticulous analysis of anatomic

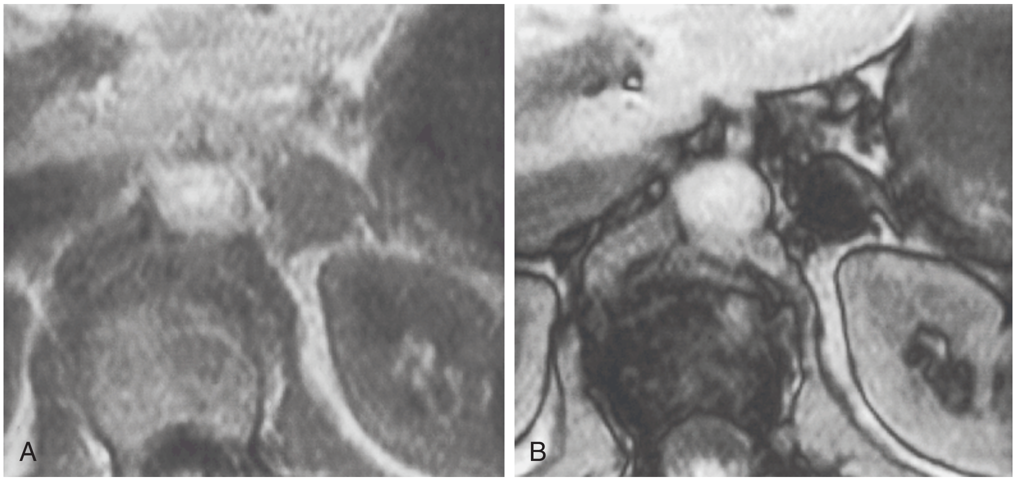

Fig. 92.7 **Adenoma.** **A,** Left adrenal gland mass is seen on this in-phase magnetic resonance image (MRI). **B,** A significant decrease in signal is seen on the out-of-phase MRI. (From Dunnick NR, Korobkin M. Imaging of adrenal incidentalomas: current status. *Am J Roentgenol.* 2002;179:559–568.)

details on CT, are essential for accurate diagnosis when there are two different pathologic processes within the adrenal gland.

KEY POINTS

- The primary use and goal for imaging is to differentiate a benign lesion from metastasis.
- Computed tomography, magnetic resonance imaging, and more recently, positron emission tomography, are useful for this distinction.
- Primary adrenal neoplasms (benign or malignant) are more challenging to evaluate.

Benign Adrenal Lesions

Adenoma. Adenoma, the most common adrenal tumor, occurs in 1.4% to 8.7% of postmortem examinations. The incidence is even higher amongst patients with hypertension or diabetes. Because most adenomas contain intracytoplasmic lipid, many have a low CT density, often approximating water on unenhanced CT (Fig. 92.8). Chemical shift MRI can also be used to distinguish many adenomas by identifying the intracytoplasmic lipid. Calcification is rare. Adenomas show early enhancement after intravenous contrast administration (Fig. 92.9). Although the degree of enhancement is not significantly different from that of other adrenal tumors, adenomas show more rapid washout of contrast than do adrenal malignancies.

Lipid-poor adenomas (LPAs), as mentioned earlier, can be problematic to characterize with CT and MRI. These comprise one third of adrenal adenomas and measure greater than 10 HU on precontrast imaging, having an absolute washout greater than 60% and relative washout greater than 40%. A study of 57 LPAs, 37 with FDG-PET scan, reported that surgery was more likely to be performed with larger tumors, masses with higher HU, and those with higher FDG uptake. Notably, oncocytic features were seen in 70% of these LPAs; therefore, a number of LPAs may be oncocytomas.[40]

It is not fully understood why some benign adrenal tumors demonstrate increased FDG uptake; however, the functional status of the tumor is presumed to be a factor, with a higher degree of metabolic activity occurring in functioning adenomas. A cohort of patients with FDG-PET scan were evaluated for differences in the metabolic signature between groups of adrenal lesions that included nonfunctioning tumors (n = 4) and functioning tumors, 11 with Cushing syndrome and four with Conn syndrome.[41] Notably, cortisol-secreting tumors had a significantly higher average SUVmax of 5.9 compared with nonfunctioning tumors (SUVmax of 4.2) and aldosterone-secreting tumors (SUVmax of 3.2). The underlying mechanism proposed on histological examination was that GLUT3 expression was higher in patients with Cushing syndrome compared with those with nonfunctioning tumors or with Conns syndrome. Another histopathology study reported that intensity of FDG uptake in adrenal adenoma was related to GLUT transporter, clear cell ratio, and higher unenhanced CT density.[42]

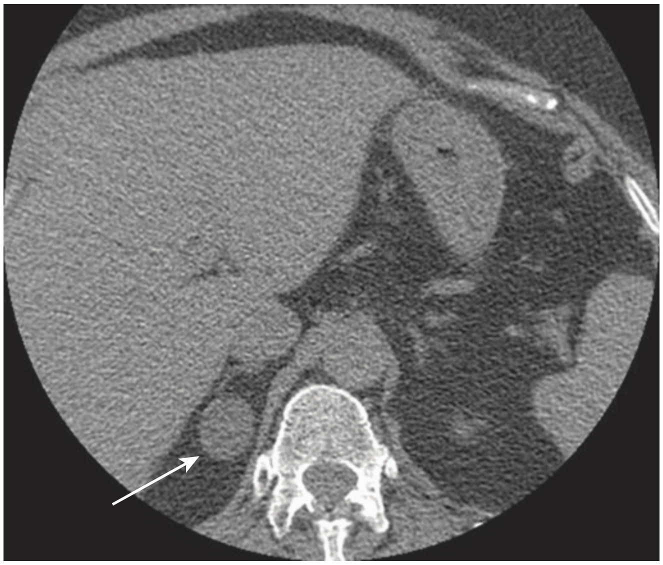

Fig. 92.8 **Lipid-rich adenoma.** Right adrenal mass (3 cm) is shown on this unenhanced computed tomography scan. Attenuation value of –4 Hounsfield units allows confident diagnosis of benign lesion, either cyst or lipid-rich adenoma.

Myelolipoma. A myelolipoma is a rare incidental benign tumor composed of bone marrow elements, accounting for 2% to 6% of primary adrenal lesions. Occasionally, large tumors or those undergoing tumor necrosis or spontaneous hemorrhage may cause flank pain.[43,44] Because these tumors contain large amounts of fat, most myelolipomas

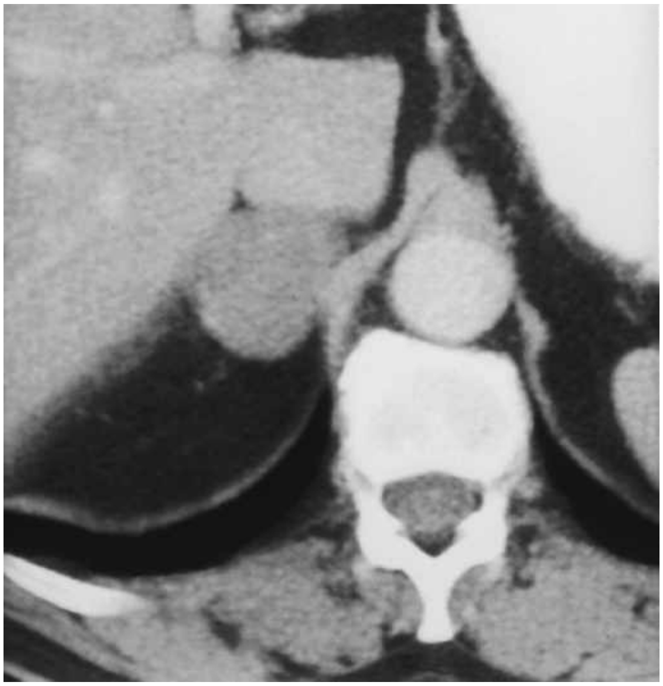

Fig. 92.9 **Adenoma.** Right adrenal gland mass (4 cm) is shown on this contrast-enhanced computed tomography examination. Attenuation value on enhanced scans is not sufficiently characteristic to distinguish benign from malignant causes. (From Dunnick NR, Korobkin M. Imaging of adrenal incidentalomas: current status. *Am J Roentgenol*. 2002;179:559–568.)

are easily recognized on CT (Fig. 92.10). The fatty components are intermixed with elements of soft-tissue density and calcification (seen in up to 20% of cases).[45,46]

The appearance of a myelolipoma on MRI also reflects the fat and bone marrow elements in the tumor. Fat exhibits high signal intensity on both non-fat-suppressed T1- and T2-weighted sequences, with loss of signal intensity on fat-suppressed images. Bone marrow elements have a low signal intensity on T1-weighted images and a moderate signal intensity on T2-weighted images. On in-phase and opposed-phase imaging, an India ink artifact can be seen at the periphery between the lesion and normal adrenal tissue, which is suggestive of a myelolipoma. Because a confident diagnosis of myelolipoma can be usually made with CT or MRI, most are treated conservatively.

Myelolipomas are not metabolically active on FDG-PET/CT (being predominately composed of fat, although mild FDG uptake can occur within the nonfatty portions of the lesions).[47]

Hemorrhage. Adrenal hemorrhage can be bilateral or unilateral. When bilateral, they are associated with anticoagulation therapy or a blood dyscrasia, and less commonly surgical stress, sepsis, large surface burns, hypotension, or rarely, trauma.[48] Unilateral adrenal hemorrhage usually is caused by blunt force abdominal trauma or has been seen occasionally after liver transplantation or by hemorrhage into a preexisting adrenal neoplasm. Adrenal vein thrombosis may also cause unilateral adrenal hemorrhage and may be a complication of adrenal vein catheterization.[49] Unilateral hemorrhage is seen more often affecting the right gland than the left.[50]

Acute or subacute adrenal hemorrhage typically has unenhanced attenuation values of 55 to 90 HU (Fig. 92.11). Follow-up studies show a diminution in size and a gradual decrease in attenuation values. The high attenuation value of a recent adrenal hemorrhage is usually readily apparent on unenhanced CT, but is indistinguishable from a solid adrenal neoplasm on contrast-enhanced CT. An adrenal mass detected on contrast-enhanced CT after trauma usually is assumed to be a hematoma; however, an unrelated adrenal neoplasm can only be excluded by serial follow-up imaging. Similarly, MRI may suggest hemorrhage depending on the age of the bleed. For example, a subacute adrenal hemorrhage can be identified by high signal intensity on T1- and T2-weighted sequences, reflecting the presence of methemoglobin.[51]

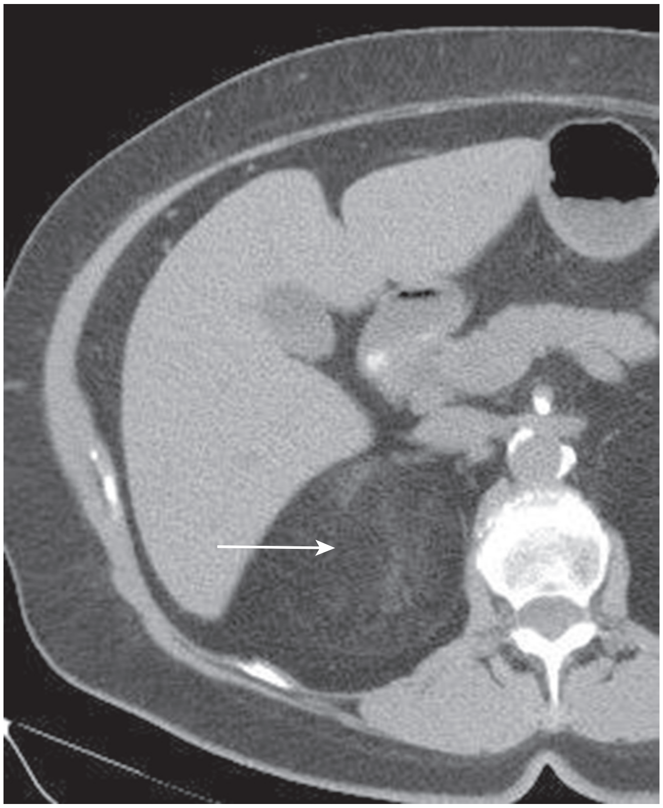

Fig. 92.10 **Myelolipoma.** Large, fatty right adrenal mass (M) is seen on this contrast-enhanced computed tomography examination.

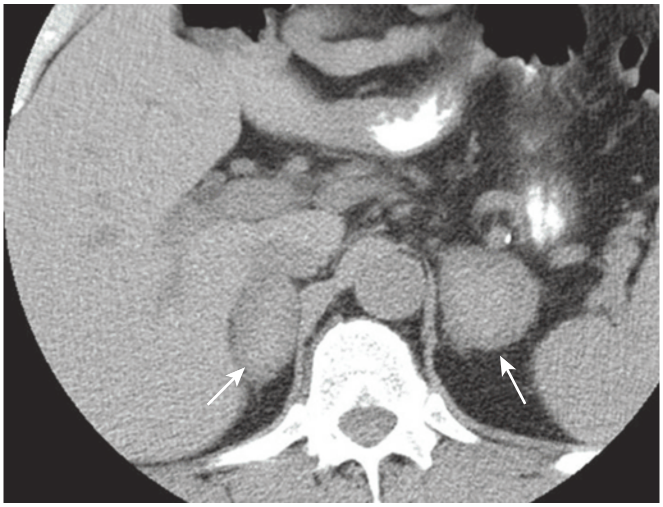

Fig. 92.11 **Adrenal insufficiency secondary to bilateral adrenal hemorrhage.** Unenhanced computed tomography shows a high attenuation mass in both adrenals *(arrows)* characteristic of acute or subacute hematoma.

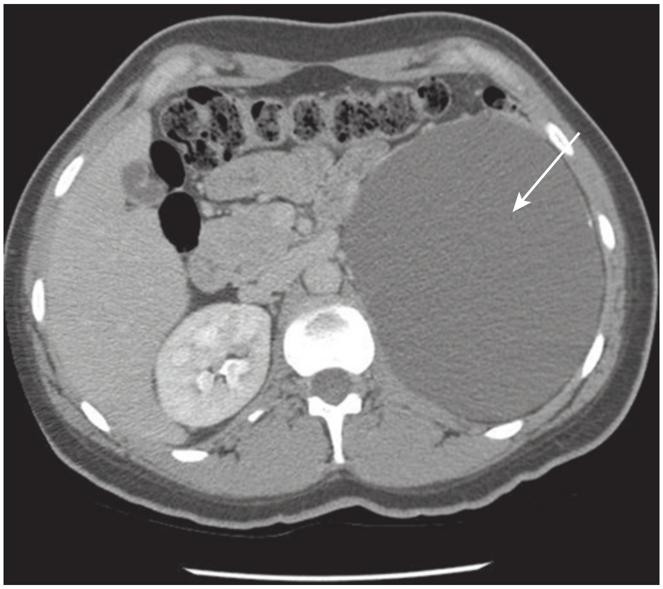

Fig. 92.12 **Adrenal cyst.** This very large homogeneous left adrenal mass measured near-water density (8 Hounsfield units). The wall is thickened but smooth and less than 3 mm.

Cyst. Adrenal cysts are uncommon lesions with a 3:1 female predilection. There are four types identified on the basis of pathologic classification: endothelial, epithelial, parasitic, and posttraumatic pseudocysts, with the endothelial cysts being the most common, accounting for 45% of adrenal cysts.[45,46,52,53] Pseudocysts are usually a sequela of prior hemorrhage and account for approximately 40% of adrenal cysts.[54]

Cysts are easily diagnosed by their imaging characteristics. On CT, cysts demonstrate a homogeneous water density (Fig. 92.12). On MRI, they tend to be T2 hyperintense and T1 hypointense and demonstrate no enhancement. Peripheral calcification is common in pseudocysts, but is rarely seen in endothelial cysts. Pseudocysts can have a complex MRI appearance, with septations, residual blood products, thicker walls, and often central hypointensity. If the cyst demonstrates soft tissue components, other causes, such as cystic metastasis and cystic pheochromocytoma, should be considered.[54]

Granulomatous Disease. Tuberculosis, histoplasmosis, and other granulomatous diseases are usually bilateral but often asymmetric. CT findings are nonspecific and include soft-tissue masses, cystic changes, and/or calcification (Fig. 92.13).[55] Although these are uncommon adrenal lesions, they should be considered in the differential diagnosis of incidental bilateral adrenal masses in the absence of a primary neoplasm or coagulopathy. Biopsy can confirm the diagnosis and identify the responsible organism.

Infectious and inflammatory conditions affecting the adrenals are another cause of false positive findings on FDG-PET due to lymphocytes and neutrophils mediating the PET uptake. Infectious FDG activity in the adrenals has been reported with cases of cryptococcus,[56,57] histoplasmosis,[58,59] adrenal tuberculosis,[60-62] and candidiasis.[63]

Hemangioma. An adrenal hemangioma is a rare, benign tumor. Hemangiomas are comprised of closely adjacent vascular channels lined with a single layer of endothelium. On CT, hemangiomas are seen as large, well-defined masses of soft tissue density with calcifications due to phleboliths or prior hemorrhage, and demonstrate heterogeneous contrast enhancement.[51,64]

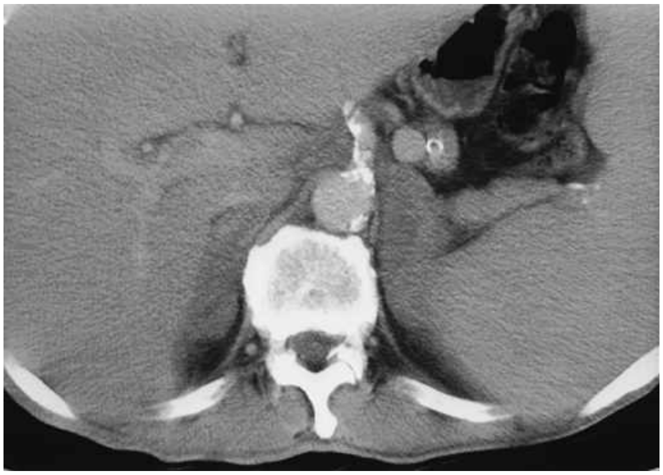

Fig. 92.13 **Histoplasmosis.** Both adrenal glands are enlarged but maintain adreniform configuration. (From Dunnick NR, Korobkin M. Imaging of adrenal incidentalomas: current status. *Am J Roentgenol.* 2002;179:559–568.)

MRI findings include a hypointense appearance relative to the liver on T1-weighted sequences, interspersed with areas of high signal intensity due to hemorrhage. On T2-weighted sequences, hemangiomas are hyperintense. Peripheral nodular enhancement that persists on delayed phases is characteristic. Tumors are usually removed because of the increased risk for hemorrhage and the inability to exclude malignancy.[65] Adrenal hemangioma will have absent uptake on FDG-PET.[66]

Ganglioneuroma. A ganglioneuroma is a benign tumor composed of Schwann cells and ganglion cells. These tumors occur anywhere along the paravertebral sympathetic plexus, and approximately 20% to 30% arise in the adrenal medulla.[67] Because they do not secrete hormones, most ganglioneuromas are detected as an incidental finding. On CT, ganglioneuromas appear as a solid adrenal mass measuring up to 11 cm. Clinically silent, extraadrenal retroperitoneal tumors may be even larger. Ganglioneuromas are typically negative with FDG-PET due to their low proliferative rate.[68]

Hypoadrenalism. Adrenal insufficiency is most commonly due to autoimmune atrophy, and imaging usually is not useful for diagnosis; the glands are small and atrophic (Fig. 92.14). In patients with adrenal insufficiency due to granulomatous infection from tuberculosis, histoplasmosis, or blastomycosis, the acute and subacute phases of disease are associated with bilateral adrenal enlargement. Heterogeneous low attenuation within the adrenal mass on enhanced CT or heterogenous high T2 signal intensity on MRI is due to caseous necrosis.[69] Unlike in patients with adrenal metastases, the enlarged glands typically retain their normal shape.

Adrenal insufficiency can also be associated with bilateral adrenal hemorrhage, and the detection of bilateral hyperattenuating masses on unenhanced CT can sometimes be the first clue to this diagnosis (Fig. 92.11). Adrenal insufficiency can also be caused by several systemic diseases, such as acquired immunodeficiency syndrome and antiphospholipid antibody syndrome. The appearance of the adrenal glands in these diseases can be variable.[70,71]

Neoplastic Adrenal Lesions

Adrenocortical Carcinoma. Adrenocortical carcinomas (ACCs) are rare tumors with a reported incidence of two cases per million.[72,73] Patients may present with abdominal pain, a palpable mass, or Cushing

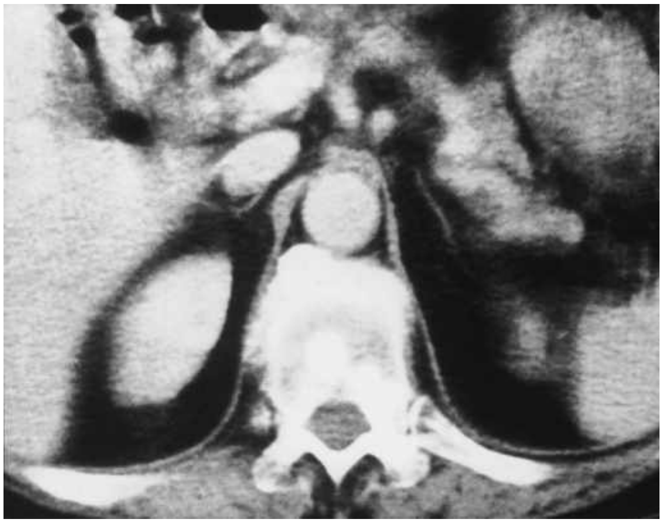

Fig. 92.14 Computed tomography shows markedly atrophic adrenal glands in a patient with adrenal insufficiency secondary to idiopathic autoimmune atrophy. (From Korobkin M, Francis IR. Adrenal imaging. *Semin Ultrasound CT MR.* 1995;16:317–330.)

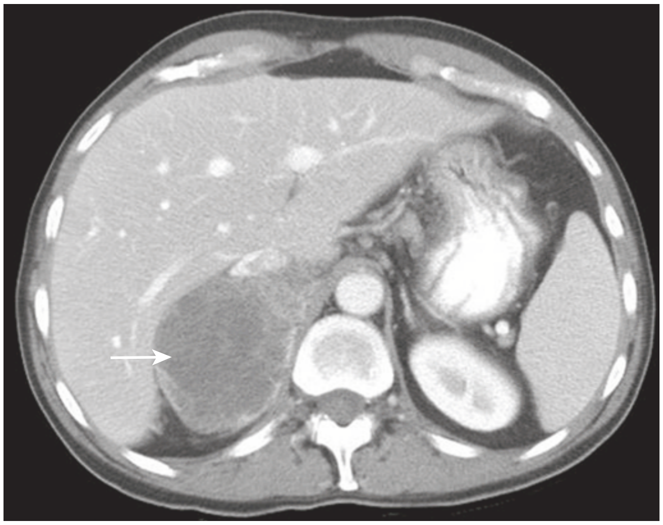

Fig. 92.15 Adrenal cortical carcinoma causing Cushing syndrome. Computed tomography scan shows a large, inhomogeneous, right adrenal mass (M).

syndrome, as approximately 50% of these tumors are functional and secrete cortisol or other steroid hormone metabolites. Other endocrine manifestations of ACC include aldosteronism, virilization, and feminization, but these are very rare. Tumors tend to be very large at the time of presentation. For this reason, any adrenal lesion larger than 4 cm in size, regardless of imaging characteristics, requires surgical consultation due to the risk of a possible underlying ACC.

The CT and MRI appearance of an ACC is a large, heterogeneously enhancing mass, commonly demonstrating central necrosis (Fig. 92.15). Calcification can be seen in 20% to 30% of cases.[72,74] Only a small number of patients with ACC have been studied with CT densitometry or chemical shift MRI. In one series that included 11 ACCs, absolute and relative enhancement loss on 10-minute delayed imaging was significantly lower than for the adenomas and similar for metastases and pheochromocytomas. In another series of seven patients with ACC, delayed enhanced images at approximately 20 minutes showed a relative percentage of enhancement washout of less than 40%, consistent with malignancy.[75]

Venous extension of tumor into the renal veins or the IVC can be identified on contrast-enhanced studies (Fig. 92.16). It is important to precisely define the cephalad extent of the intravenous tumor, as this defines the point where the surgeon can gain vascular control of the tumor.[76]

It is important to remember that a large adrenal metastasis, or even a pheochromocytoma, can have an imaging appearance identical to that of an ACC. In the absence of metastases, differential diagnosis is usually carcinoma versus adenoma. The larger the mass, the greater the likelihood of carcinoma, although on rare occasions adenomas can be greater than 5 cm and can have large regions of hemorrhage, necrosis, and calcification.

ACC has been consistently demonstrated to display high metabolic activity on FDG-PET imaging. Due to its poor prognosis, marked by high incidence of disseminated disease (in 50% of patients) at presentation, and the high rate of recurrence after initial complete resection (73%–86% at 2 years), patients undergo extensive and serial imaging evaluation for staging and restaging of disease. In a study of 68 patients with adrenal malignancy that included ACC, pheochromocytoma, NB, and lymphoma, the authors reported that FDG-PET had better accuracy than CT (93.4% vs. 75%) for ACC, and that SUVmax was a significant predictor of outcomes in these malignant adrenal masses.[77]

In 48 patients with confirmed ACC recurrence, FDG-PET had lower sensitivity than CT for liver and lung recurrence, although it had higher specificity than CT and better positive predictive value.[78] Therefore, FDG-PET is a useful complementary tool in managing surveillance of ACC after primary surgery and management. As mentioned earlier, ACC is a malignant highly aggressive neoplasm with propensity for tumor invasion into the IVC, causing pulmonary embolism, which can be depicted on FDG-PET/CT.[79] With respect to prognosis, Satoh and colleagues evaluated 30 patients with ACC using metabolic tumor volume (MTV), total lesion glycolysis (TLG), and SUVmax and found that patients with high MTV (>87 mls), TLG (>229), or SUVmax (>8.8) had worse outcomes for both progression-free and overall survival.[80]

Overexpression of chemokine receptor 4 (CXCR4) in ACC is a potential diagnostic and therapeutic receptor target.[81] FDG-PET was compared to ^{68}Ga-pentixafor PET, with both studies performed within a week of each other. In 30 patients with disease, the PET studies in five (17%) were complementary and in 10 (33%) were comparable. In 13 (43%), more lesions were found with FDG-PET than with ^{68}Ga-pentixafor PET. Overall, 70% of patients with advanced metastases from the ACC may be suitable for CXCR4-directed therapy (radiotherapy or pharmacotherapy). CXCR4 positivity in ACC correlates with expression and quantification of metastases.[82]

Pheochromocytoma. Adrenal pheochromocytomas and paragangliomas, arising from extraadrenal tissues, are rare tumors derived from the sympathomedullary cells of postganglionic sympathetic neurons. The majority arise within the adrenal medulla or in an extraadrenal location near the celiac axis or aortic bifurcation (organ of Zuckerkandl). Those that are catecholamine-secreting result in the classic signs and symptoms of hypertension, tachycardia, headaches, palpitations, diaphoresis, and chest pain. Although many patients present with some or all of these manifestations of excess catecholamine production, approximately 8% to 10% of tumors are silent and incidentally detected by imaging studies. A significant proportion of these tumors are found to be malignant once evidence of metastatic spread is documented, usually with imaging.

Although pheochromocytomas were traditionally taught as following the rule of 10s (10% being multiple, 10% being inherited, 10% being extraadrenal in location, and 10% being malignant), more

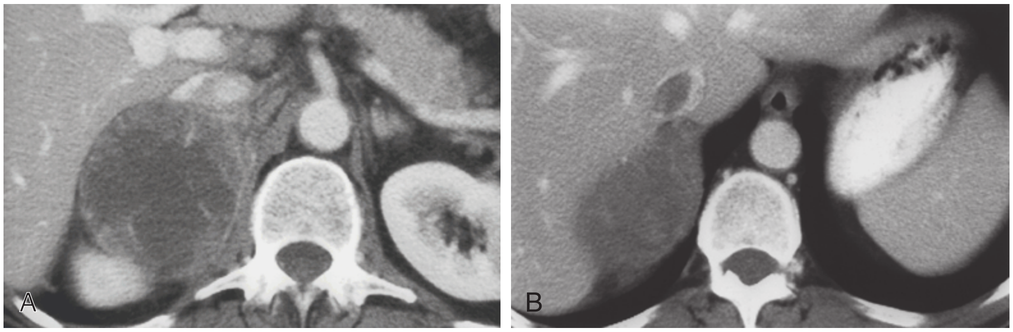

Fig. 92.16 **Adrenal cortical carcinoma. A,** Contrast-enhanced computed tomography examination shows a 9-cm right adrenal mass. Irregular wall and low-density center indicate necrosis. **B,** More cephalad image in same examination reveals tumor extension into inferior vena cava. (From Dunnick NR, Korobkin M. Imaging of adrenal incidentalomas: current status. *Am J Roentgenol.* 2002;179:559–568.)

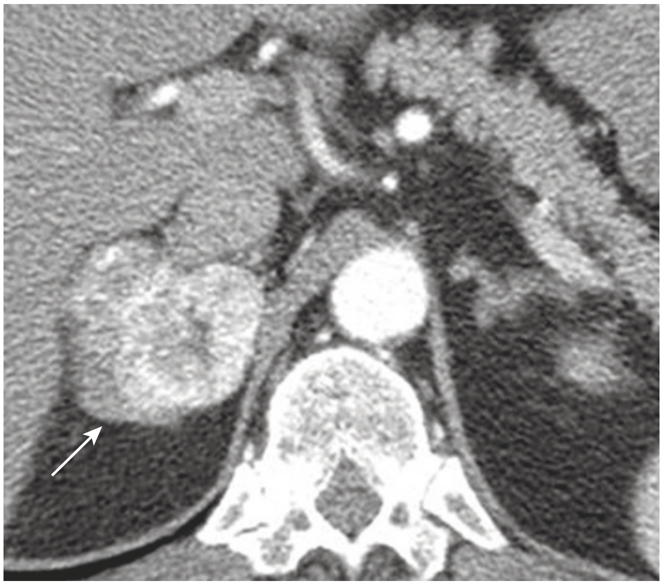

Fig. 92.17 Intravenous contrast-enhanced computed tomography shows a right adrenal pheochromocytoma (P) with areas of necrosis.

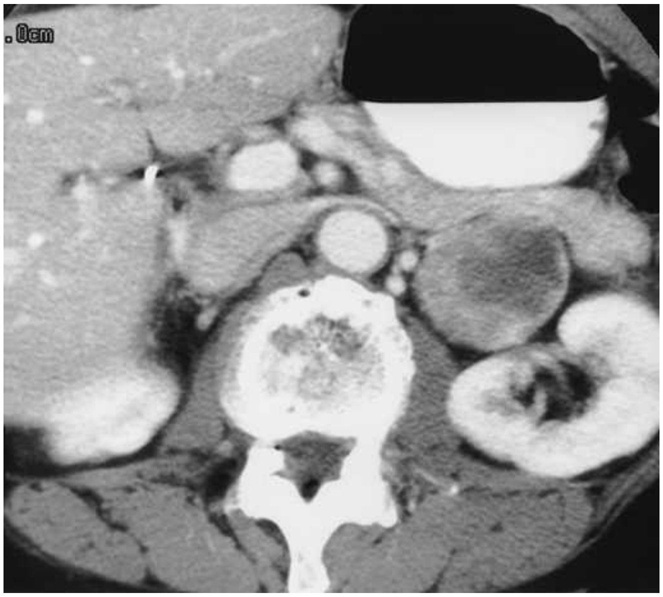

Fig. 92.18 **Retroperitoneal extraadrenal pheochromocytoma.** Enhanced computed tomography shows an inhomogeneous enhancing mass medial to the left kidney. A normal left adrenal was demonstrated on scans cephalad to this mass.

contemporary understanding of genetic predisposition has identified closer to 40% of cases as being inherited and associated with disorders including multiple endocrine neoplasia (MEN) syndromes, neurofibromatosis, von Hippel–Lindau (VHL), or familial pheochromocytoma.[83]

The diagnosis of pheochromocytoma can be confirmed by elevated blood or urine levels of the catecholamines epinephrine and norepinephrine or their metabolites. Localization of a pheochromocytoma is essential, because surgical resection of the tumor can be curative. On CT, pheochromocytomas typically range from 2 to 5 cm and demonstrate heterogeneous attenuation (usually >10 HU on unenhanced images) due to necrosis or hemorrhage, particularly when they are larger in size. Imaging of pheochromocytomas with contrast-enhanced CT has historically been associated with contrast-induced hypertensive crisis; however, use of nonionic contrast agents has eliminated this concern. On contrast-enhanced CT, pheochromocytomas typically demonstrate heterogeneous enhancement similar to that seen in ACC or metastases (Fig. 92.17). Oral contrast opacification of the gastrointestinal tract can be occasionally helpful for the detection of extraadrenal pheochromocytomas/paragangliomas, because unopacified bowel may rarely be mistaken for a "mass" and may mimic these tumors (Fig. 92.18).[84] Unusual locations of paragangliomas have also been reported, such as the rare, intrapericardial paraganglioma adjacent to or involving the left atrium (Fig. 92.19).

On MRI, most pheochromocytomas are hypointense on T1-weighted images and markedly hyperintense on T2-weighted images. There is considerable overlap of signal on T2-weighted images with other neoplasms, including ACC, in up to 33% of cases. This overlap on T2-weighted imaging may be related to necrotic or cystic areas that are commonly seen in these tumors. Contrast-enhanced MRI is useful for demonstrating the presence or absence of intracaval extension of adrenal pheochromocytoma. MRI is also useful for the evaluation of extraadrenal paragangliomas that can be seen from the neck to the bladder.

^{123}I-MIBG can be used to image pheochromocytoma and paraganglioma with high specificity, thus confirming their origin from the neural crest, with the additional benefit of whole-body screening to identify multifocal and/or remote metastatic disease (Fig. 92.20). A metaanalysis found MIBG scintigraphy to have high sensitivity (94%) and specificity (95%) for imaging pheochromocytoma/paraganglioma.[85] MIBG scintigraphy is clinically useful in depicting diagnostically elusive and often small paragangliomas because of their close relationship to other structures and remote locations (extraadrenal sites), screening from the base of the skull to the pelvis (Fig. 92.21). In malignant pheochromocytoma/paraganglioma studied with MIBG, the most common sites of metastatic disease are the skeleton, lymph nodes, lung, and peritoneum. Importantly, MIBG imaging is not particularly useful in head and neck paragangliomas, as these are tumors are of parasympathetic origin that lack chromaffin cells and are nonsecretory; these neoplasms are better imaged with ^{68}Ga-DOTAtate or ^{18}F-DOPA PET.[86]

A range of PET radioisotopes such as ^{18}F-FDG, ^{18}F-DA, ^{18}F-DOPA, and ^{11}C-HED (Fig. 92.24) have been successfully used to image pheochromocytoma and paraganglioma and can be useful in cases when the disease does not show strong MIBG uptake.[87] Most pheochromocytomas, whether benign or malignant, can be imaged with FDG-PET, although focal FDG uptake is found in greater percentage of malignant than benign pheochromocytomas. Shulkin et al. reported that 22 of 29 patients with pheochromocytoma could be identified with FDG-PET, and that MIBG-negative pheochromocytomas were depicted with FDG, a finding that has been confirmed by others.[88] Timmers et al. found that FDG-PET had a sensitivity of 77% and a specificity of 90% in 216 patients with suspected pheochromocytoma/paraganglioma and outperformed both MIBG and CT/MRI.[89] In one study, the combination of FDG-PET and apparent diffusion coefficient on MRI was useful to separate 11 pheochromocytomas from 22 other benign tumors.[90] Preoperative PET may find extra lesions prior to surgical resection of pheochromocytoma.[91]

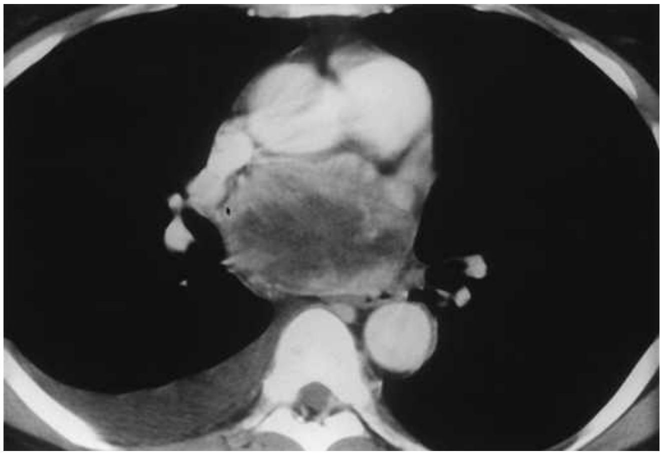

Fig. 92.19 Intrapericardial extraadrenal pheochromocytoma. Enhanced computed tomography shows an inhomogeneous mass in the expected location of the left atrium. Metaiodobenzylguanidine scan was positive in this location. (From Hamilton BH, Francis IR, Gross BH, et al. Intrapericardial paragangliomas [pheochromocytomas]: Imaging features. *Am J Roentgenol.* 1997;168:109–113.)

Metabolic subtyping of pheochromocytoma with FDG-PET has been reported.[92] Metabolic uptake is higher for malignant than benign pheochromocytoma and for extraadrenal paraganglioma than adrenal sites. The degree of FDG uptake in pheochromocytoma depends on genetic mutation. In genetic syndromes, cluster 1 genes (*SDHx, VHL*) have higher FDG uptake than cluster 2 genes (*RET, NF1*).[93] The use of FDG-PET for screening for *SDHx* mutation carriers has high sensitivity and intermediate specificity,[94] and FDG-PET use has been explored for patients with VHL, patients with MEN2, and for screening for pheochromocytoma in NF1 patients.[95]

Fottner et al. reported an ^{18}F-DOPA-PET sensitivity of 98% (62/64 lesions) and specificity of 100%, much higher compared to an MIBG sensitivity of only 53% (34/64 lesions) and specificity of 91%.[96] ^{18}F-DOPA-PET was reported to be markedly avid in a more recently described genetic predisposition due to MYC-associated factor X (MAX) pheochromocytoma.[97]

Studies of ^{18}F-DA-PET for imaging pheochromocytoma/paraganglioma show high sensitivity and specificity.[98] Discordant results with MIBG, ^{18}F-FDG, ^{18}F-DA, and ^{18}F-DOPA imaging appear to depend on tumor phenotype and are most likely related to the specific underlying mutation. In one comparative study of different molecular imaging

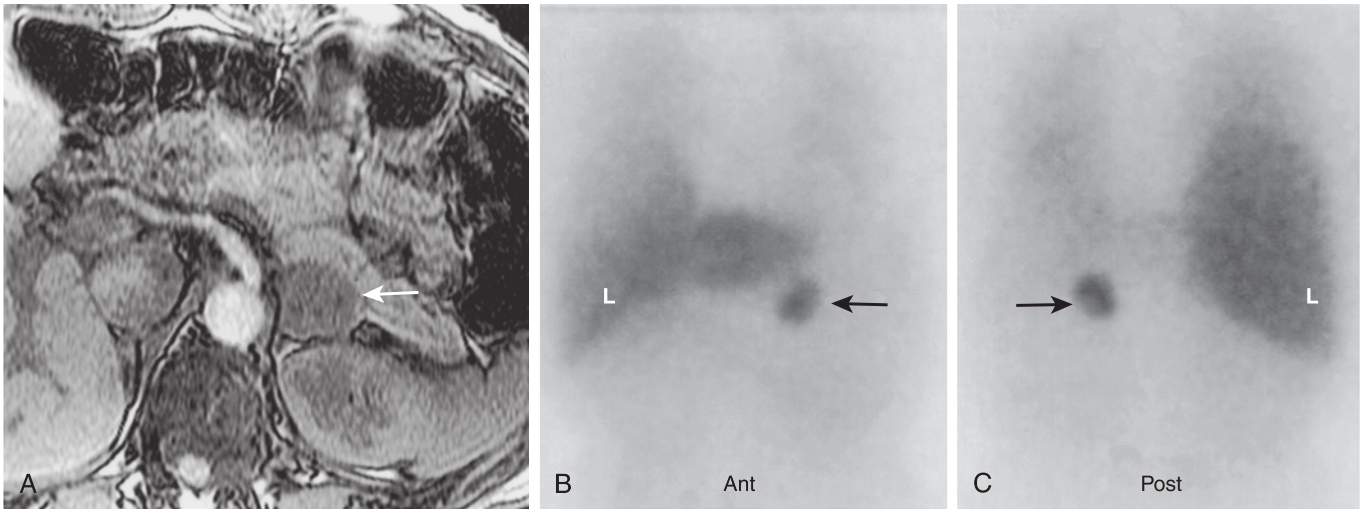

Fig. 92.20 **Left adrenal pheochromocytoma demonstrated by ^{123}I-metaiodobenzylguanidine (MIBG) and magnetic resonance imaging (MRI).** A 50-year-old female with hypertension, a history of neurofibromatosis, elevated plasma catecholamines, and a 3-cm left adrenal mass on MRI. **A,** Abdominal MRI, transverse section, with left adrenal pheochromocytoma *(white arrow)*. **B,** Anterior abdominal ^{123}I-MIBG scan with normal liver (L) uptake. The *black arrow* indicates intense, focal tracer uptake in the region of the left adrenal gland. **C,** Posterior abdominal ^{123}I-MIBG scan. Fig. 92.21 **A 53-year-old man with uncontrolled hypertension and catecholamine hypersecretion, suspected for pheochromocytoma.** ^{123}I-metaiodobenzylguanidine (MIBG) composite anterior (**A**) and posterior (**B**) whole-body images at 24 hours postinjection show focal intense activity in the region of the left adrenal gland *(arrow)*. **C,** Axial computed tomography (CT), and fused single-photon emission CT (SPECT)/CT images confirm a left adrenal pheochromocytoma with intense ^{123}I-MIBG uptake *(arrowheads)*. There is also preaortic soft tissue nodule with intense ^{123}I-MIBG uptake *(arrows)* on the SPECT/CT that may represent an extraadrenal paraganglioma or, less likely, a metastatic retroperitoneal lymph node indicating malignant disease. (From Youssef E, Wong KK. Hybrid SPECT-CT endocrine scintigraphy: a pictorial review. AUR, Annual Meeting in San Antonio, Texas, 2011.)

radiotracers, Timmers et al. investigated 30 patients with the succinate dehydrogenase subunit B (*SDHB*) germline mutation and metastatic pheochromocytoma/paraganglioma.[89] They found that ^{18}F-FDG-PET had a sensitivity of 100% that exceeded ^{18}F-DOPA (88%), MIBG (80%), and somatostatin receptor scintigraphy (SRS) (81%). At least 90% of the lesions that were negative on ^{18}F-DOPA and MIBG imaging were depicted with ^{18}F-FDG, making it the imaging agent of choice in patients with *SDHB* germline mutations.

PET imaging of ^{68}Ga-DOTA-conjugate peptides such as ^{68}Ga-DOTAtoc (DOTA^0-1NaI^3-octreotide), ^{68}Ga-DOTAnoc (DOTA^0-Tyr^3-octreotide) and ^{68}Ga-DOTAtate (DOTA^0-Tyr^3-octreotate) has brought dramatic improvement in sensitivity and spatial resolution and is preferred for NET localization and staging studies. Further advantages are same-day imaging protocols and availability of whole-body nondiagnostic CT component, use of newer-generation DOTA chelator with improved affinity for SSTR2, and ability to predict efficacy of ^{177}Lu or ^{90}Y-radionuclide labeled somatostatin analogs. ^{68}Ga-DOTANOC-PET imaging of pheochromocytoma has been reported and can successfully image metastatic pheochromocytoma/paraganglioma in MIBG-negative patients (Fig. 92.22).[10,99] Widespread availability of ^{68}Ga-DOTANOC-PET since 2016 in North America has resulted in it largely replacing ^{111}In-octreotide for imaging of NETs. It has high sensitivity for pheochromocytoma/paraganglioma; however, specificity is limited, as many nonendocrine tumors (e.g., breast cancer, meningioma, lymphoma), granulomatous and inflammatory diseases (e.g., sarcoidosis, tuberculosis), and autoimmune diseases (rheumatoid arthritis) express type 2 somatostatin receptors. Somatostatin receptor PET imaging is most useful when MIBG scanning is negative in metastatic pheochromocytoma/paraganglioma or when other neuroendocrine neoplasms are suspected (Fig 92.23).[95,100,101]

Lymphoma. Primary lymphoma of the adrenal glands is rare, and secondary involvement of the adrenals is seen more often in patients with non-Hodgkin lymphoma than in Hodgkin lymphoma.[102] In secondary lymphoma, adrenal involvement is often bilateral, and other retroperitoneal disease is usually present. On CT, there is homogeneous

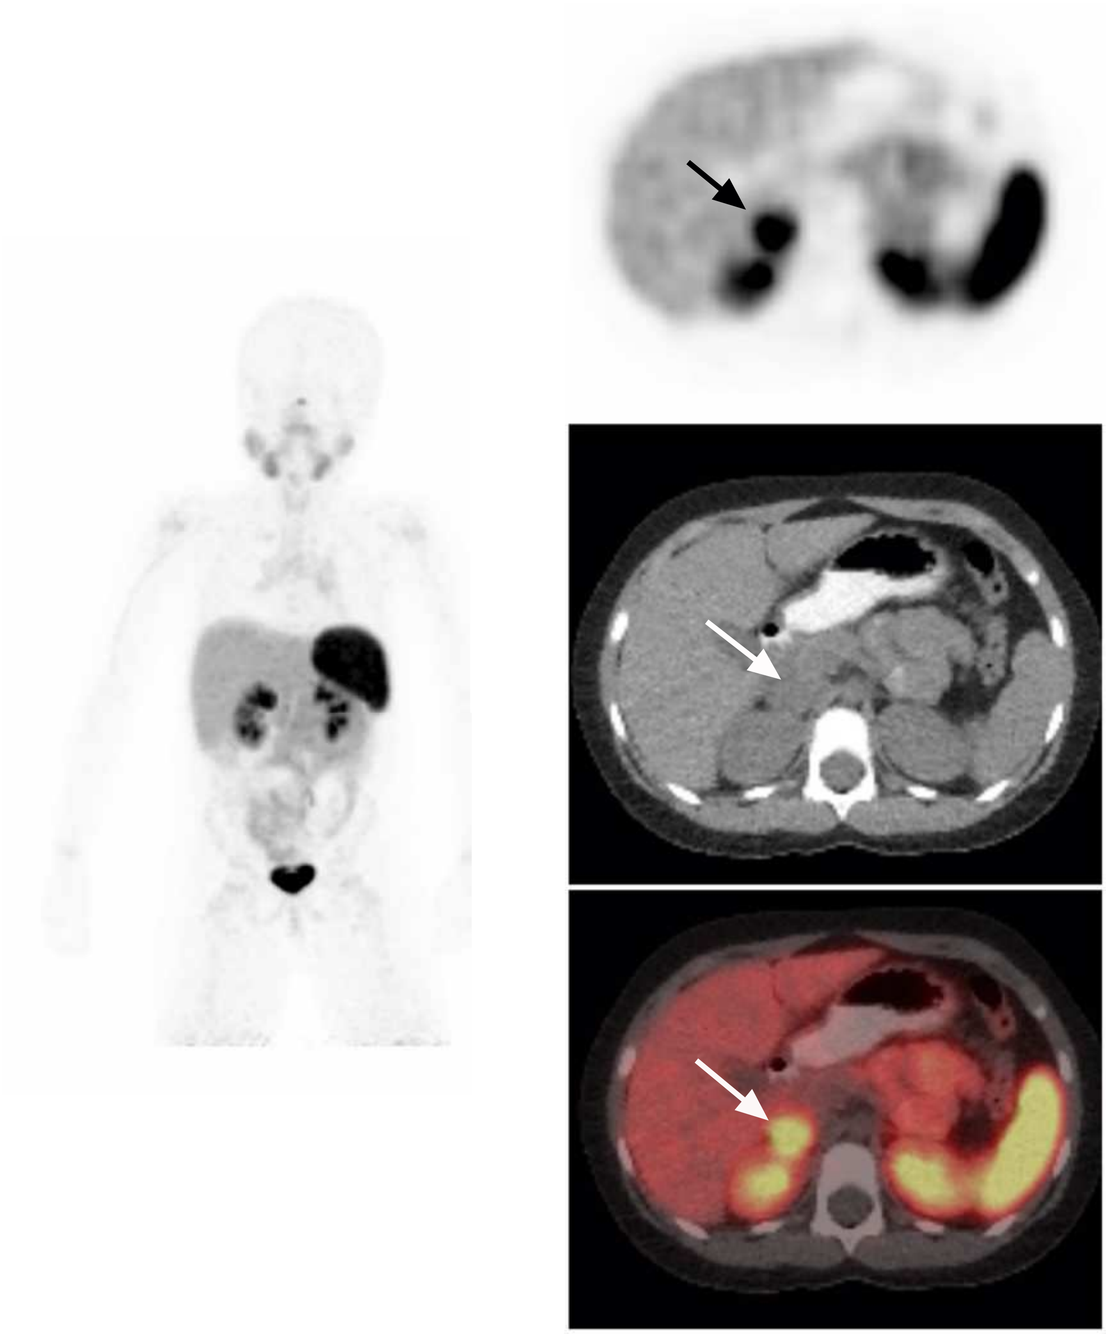

Fig. 92.22 **^{68}Ga-DOTA-tate positron emission tomography/computed tomography scan in a patient with elevated catecholamines and a right-sided adrenal mass.** Pheochromocytoma was confirmed on adrenalectomy specimen.

enlargement of the adrenal gland with variable enhancement.[103] On MRI, lymphoma is characterized by hypointense signal on T1-weighted images and heterogeneous hyperintensity on T2-weighted images with minimal postcontrast enhancement.

FDG-PET/CT is a useful imaging modality for both secondary and primary adrenal lymphoma.[104-108] In secondary lymphoma, the adrenal masses typically have limited washout and high SUV values.[109] They are most often due to diffuse large B cell lymphoma and are well-defined masses with preserved adreniform shape, having mean SUV 18.6 and size greater than 3 cm. FDG-PET was reported in 28 patients with primary adrenal lymphoma, with disease usually manifesting as intensely hypermetabolic adrenal masses. FDG-PET provides prognostic information for primary adrenal lymphoma,[110] with poor overall survival of 61.9% at 2 years despite chemotherapy (Fig 92.25).[111]

Metastases. The adrenal glands are a common site of metastatic disease, which is found in approximately 27% of postmortem examinations of patients with malignant neoplasms of epithelial origin.[112] The most common neoplasms that metastasize to the adrenal glands are carcinomas of the lung and breast, and melanoma. Small metastases

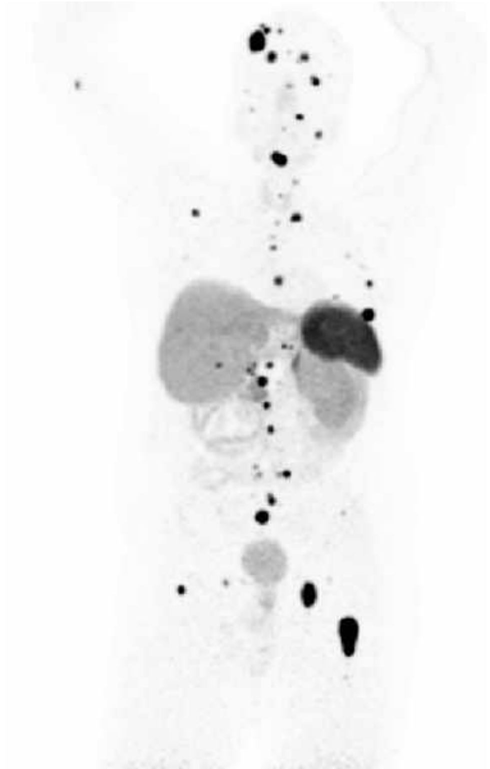

Fig. 92.23 ^{68}Ga-DOTA-tate positron emission tomography maximum intensity projection images in a 25-year-old man with metastatic paraganglioma, demonstrated intensely avid uptake in multiple osseous lesions scattered in the skeleton.

(Figs. 92.26 and 92.27) are often homogenous on contrast-enhanced CT or MRI, whereas larger metastases often appear heterogeneous due to necrosis and/or hemorrhage. Calcification is rare in adrenal metastases. Intracellular lipid can be seen in metastases from clear cell renal cell carcinoma and hepatocellular carcinoma. In addition, adrenal washout characteristics need to be interpreted with caution in patients with suspected metastases from hepatocellular carcinoma, renal cell carcinoma, and NET, as these lesions may demonstrate washout characteristics similar to that of benign adrenal adenomas.[113]

In a metaanalysis for staging/restaging lung cancer that included 707 patients from nine studies, metabolic imaging with FDG-PET had a pooled sensitivity of 88% and specificity of 90.8% for detection of metastatic disease.[114] It is recognized that in cancer patients with oligometastatic disease to the adrenal (i.e., solitary metastasis to the adrenal) adrenalectomy can have a survival advantage.[115,116] In a retrospective study of 289 patients undergoing adrenalectomy, 39 (13%) had suspected oligometastatic disease due to a positive adrenal FDG-PET.[117] In 28/39 (71.8%) of these patients, the oligometastasis was confirmed at adrenalectomy; history of primary lung cancer and SUVmax greater than 2.65 increased the odds ratio of metastatic disease. However, notably in this series, ten benign cortical adenomas and one nonfunctioning pheochromocytoma had positive PET findings, leading to a 28.2% false-positive rate in this setting (Figs. 92.28 and Fig 92.29).

Neuroblastoma. Neuroblastoma (NB), a malignant tumor composed of primitive neuroblasts, is the most common extracranial solid malignancy of children, representing 8% to 10% of pediatric cancers. The mean age of diagnosis is 15 months, and the majority occur in infancy and early childhood.[118] While these tumors may occur anywhere along the sympathetic plexus, the most common site for primary NB is the adrenal gland, accounting for approximately 35% to 40% of cases.[119] Unfortunately, metastases are present in over half of pediatric patients at diagnosis.

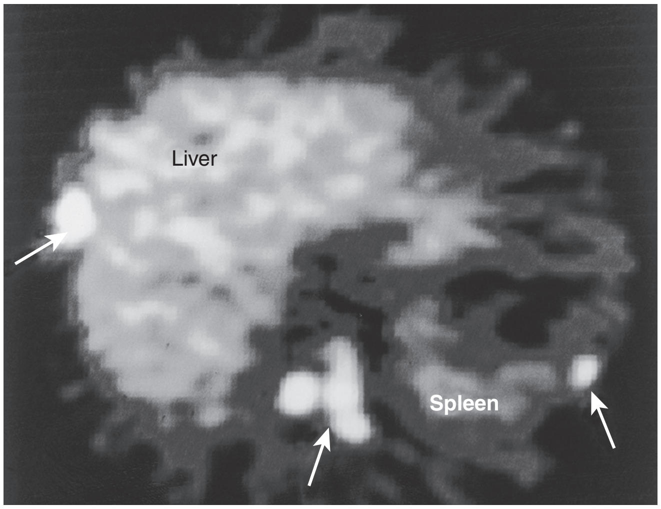

Fig. 92.24 ^{11}C-Hydroxyephedrine (^{11}C-HED) positron emission tomography scan in a patient with malignant pheochromocytoma. Multiple areas of increased uptake are seen in the liver, abdomen, and spleen *(arrows)*. (From Gross MD, Shapiro B. Adrenal scintigraphy. In: Khalkhali I, Maublant J, Goldsmith S, eds. *Nuclear Oncology*. Philadelphia: Lippincott, Williams & Wilkins; 2000:472.)

NB in adults, though rare, usually have imaging findings that are similar to those in children, with disseminated disease at presentation being common. On CT, NB appears as a large, irregular, and heterogeneous mass due to necrosis and/or hemorrhage. Calcification is common and can be seen in 80% to 90% of cases.[120] On MRI, NB typically demonstrates heterogeneous hypointense signal on T1-weighted images and hyperintense signal on T2-weighted images with variable and heterogeneous enhancement. NB can be aggressive and infiltrative, causing narrowing and encasement of adjacent vessels. Invasion of adjacent soft tissues and organs can also occur.[121]

^{123}I-MIBG diagnostic imaging is an established modality for diagnosis, staging, and treatment response assessment of NB, as well as for determining suitability of targeting of metastatic disease for subsequent ^{131}I-MIBG treatment.[122] ^{123}I-MIBG is more accurate than bone scan for detection of osseous metastatic disease in NB.[123] More recently, ^{68}Ga-DOTATATE-PET/CT has been found to be positive in just over two thirds of patients with refractory NB, in six of eight patients in each of two small pilot studies.[124,125] Furthermore, ^{68}Ga-DOTATATE-PET/CT detected additional sites of disease compared with ^{123}I-MIBG in three out of eight patients.[125] ^{68}Ga-DOTATATE-PET/CT imaging has that potential to inform on suitable targeting of radionuclide treatment of NB with 177Lu-DOTA peptides.[124]

Cushing Syndrome. Cushing syndrome results from excessive glucocorticoids, resulting in characteristic clinical signs and symptoms. Cushing syndrome refers to the clinical and metabolic disorder regardless of the underlying cause. The most common etiology is iatrogenic steroid administration. Endogenous Cushing syndrome is due to overproduction of cortisol by the adrenal cortex, caused by (1) excess production of ACTH by a pituitary tumor; (2) benign or malignant steroid-producing adrenocortical neoplasm; or (3) bilateral adrenal hyperplasia secondary to an ectopic source of ACTH production. Very rare causes of ACTH-independent bilateral hyperplasia have also been described. Strictly speaking, Cushing disease refers only to

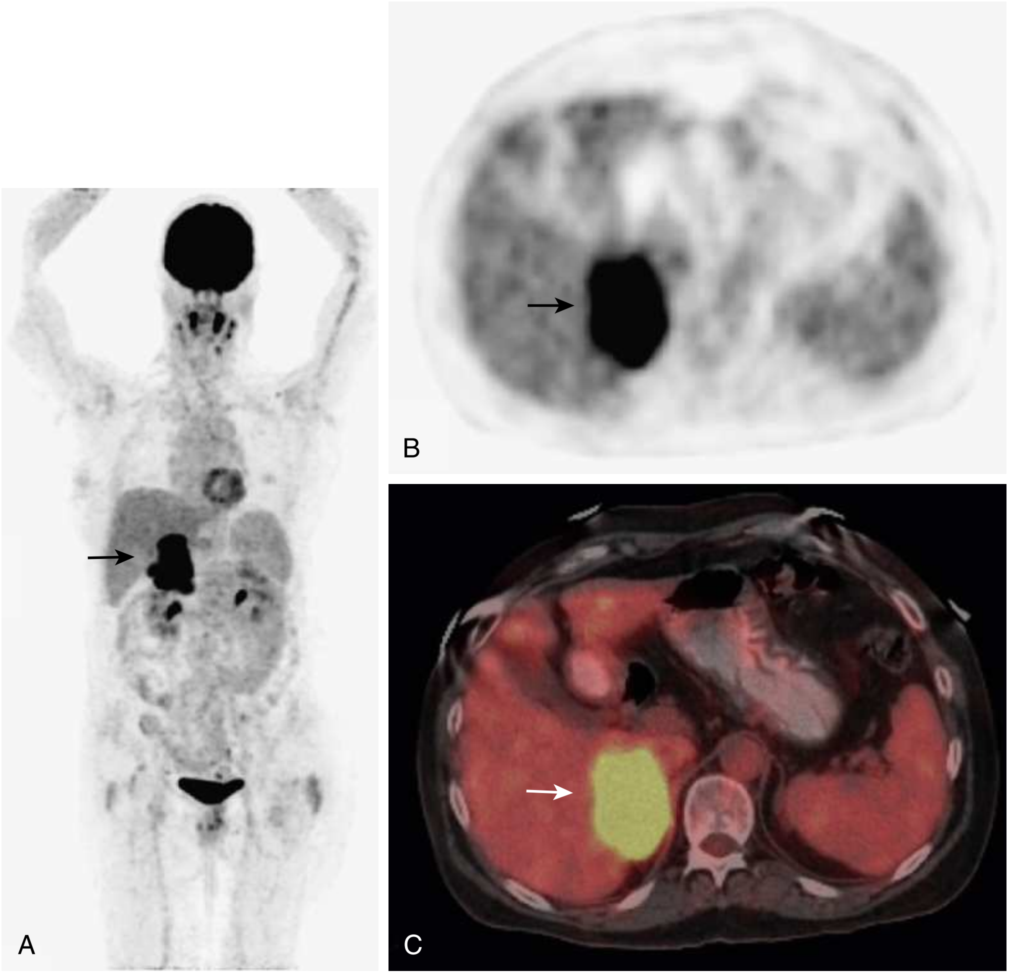

Fig. 92.25 **(^{18}F)-fluorodeoxyglucose (FDG) positron emission tomography/computed tomography (PET/CT) in a 53-year-old woman with chronic myeloid leukemia, status post–bone marrow transplantation.** Maximum intensity projection image (**A**), axial PET (**B**), and fusion PET/CT (**C**) demonstrate a 6.5 x 5.5 cm right suprarenal mass *(arrows)* with intensely increased FDG uptake (maximum standard uptake value = 17.1) above liver background (liver mean standard uptake value = 2.8). Histopathology specimen of the resected mass was compatible with a hematolymphoid malignancy, an extramedullary myeloid tumor. (From Wong KK, Arabi M, Bou-Assaly W, et al. Evaluation of incidentally discovered adrenal masses with PET and PET/CT. *Eur J Radiol.* 2012;81:441–450.)

bilateral adrenal hyperplasia due to ACTH hypersecretion by a pituitary adenoma.

Most cases of Cushing syndrome (up to 85%) are due to excess ACTH production from pituitary or ectopic sources. The adrenal glands may be normal or show diffuse bilateral gland thickening and nodularity on CT, a finding indicative of hyperplasia. A small percentage of patients (12%–15%) with Cushing disease demonstrate multiple or, less commonly, single macronodules, varying in size from several millimeters to as much as 7 cm in diameter.[126] If macronodular adrenal hyperplasia is characterized by a single dominant nodule, this entity may be confused with a unilateral autonomous adrenal adenoma, leading to inappropriate unilateral adrenalectomy. Additional small nodules or diffuse overall enlargement of both glands are usually present; however, correlation with the biochemical findings allows the correct diagnosis to be made.

A much rarer form of macronodular adrenal hyperplasia is ACTH-independent disease. Two unique CT and MRI features of this disorder are the large mass of cortical tissue and the size of individual nodules (Fig. 92.30).[127] The size of the nodules can suggest alternate diagnoses such as bilateral metastases or bilateral adenomas, but in the presence of Cushing syndrome, the appearance is practically pathognomonic of ACTH-independent macronodular adrenal hyperplasia, and bilateral adrenalectomy is indicated as optimal therapy, on the basis of clinical and CT findings.

Approximately 15% of cases of ACTH-dependent Cushing syndrome are due to ectopic ACTH secretion from a nonpituitary source. The most common sources of ectopic ACTH-producing tumors are small cell lung carcinomas and bronchial carcinoids. However, the diagnosis of patients with occult sources of ACTH secretion presents a difficult diagnostic challenge. In one study, five of eight bronchial carcinoid tumors measured between 4 and 10 mm in diameter, and thin-section CT was required to detect these small tumors. Less common sources of ectopic ACTH production include elusive islet cell tumors of the pancreas, pheochromocytomas, medullary thyroid carcinomas, and thymic carcinoids. Another study that included molecular imaging found that the source of ectopic ACTH-secreting tumors in descending order was the lung (55.3%), pancreas (8.5%), mediastinum thymus (7.9%), adrenals (6.4%), and gastrointestinal tract (5.4%). Bronchial NETs were the most common (54.8%) etiology. However, imaging was only moderately successful in localizing

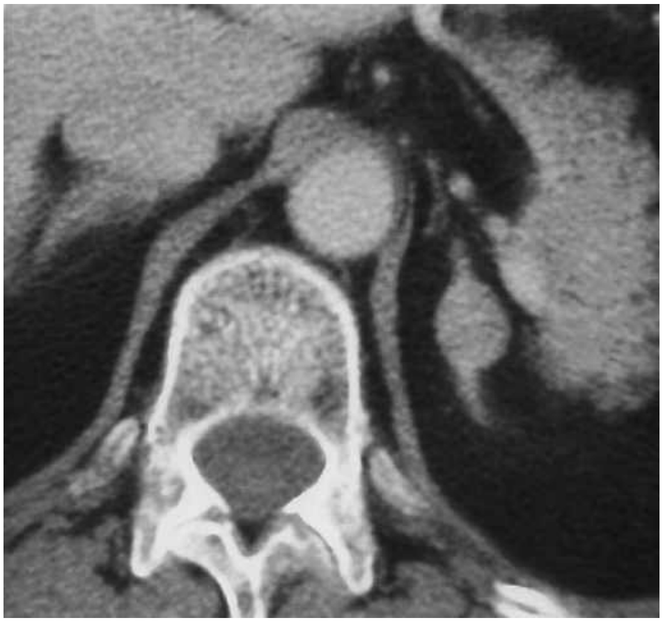

Fig. 92.26 Metastasis from renal carcinoma in a 31-year-old woman. Small, homogeneous left adrenal mass is seen on this contrast-enhanced computed tomography examination. (From Dunnick NR, Korobkin M. Imaging of adrenal incidentalomas: current status. *Am J Roentgenol.* 2002;179:559–568.)

the tumor site (CT 66.2%, MRI 51.5%, FDG-PET 51.7%, 18F-DOPA 57.1%, and MIBG 30.8%).[128] The best imaging modality for bronchial carcinoid and other NETs causing ectopic ACTH secretion was ^{68}Ga-DOTATATE-PET, with a sensitivity of 81.8%,[129] whereas FDG-PET performs better for detection of small cell lung cancer.[130]

Up to 30% of cases of Cushing syndrome are due to an ACTH-independent adrenocortical neoplasm; approximately two-thirds of these are due to adrenal adenomas, and the other one-third to ACCs. These tumors are easily detectable on both CT and MRI. Adrenocortical adenomas are nearly always less than 5 cm in diameter, typically 2 to 2.5 cm in size, and have a nonspecific morphologic appearance (Fig. 92.31).

Primary Aldosteronism. Primary aldosteronism (PA) is characterized by moderate to severe hypertension caused by unregulated secretion of aldosterone with elevated levels of serum and urinary aldosterone, hypokalemia, and suppressed plasma renin activity. A solitary aldosterone-producing adenoma (APA) is present in approximately 70% of patients, and surgical or laparoscopic adrenalectomy corrects hypertension and hypokalemia in 75% to 90% of cases (Fig. 92.32).[131] The majority of the remainder of patients have idiopathic hyperaldosteronism (IHA) from bilateral adrenal hyperplasia. Unlike in patients with unilateral APA, adrenalectomy rarely cures hypertension and biochemical abnormalities, and as a result these patients are managed medically. It is essential, therefore, to distinguish APA from IHA at the outset.[132]

CT evaluation is often problematic, because unilateral aldosteronomas may be associated with ipsilateral or contralateral nonfunctioning adenomas, resulting in misdiagnosis of "nodular" adrenal hyperplasia.[133] In addition, very rarely, bilateral hyperplasia may have a predominant unilateral macronodule and contralateral gland thickening that may lead to an erroneous diagnosis of a unilateral aldosteronoma.

Doppman and colleagues[134] demonstrated that CT cannot reliably differentiate APA from IHA whenever bilateral adrenal nodules are identified. In their series, six of 21 patients with APA were incorrectly diagnosed on CT as having IHA due to the presence of non-aldosterone-secreting nodules (nonfunctioning adenomas), in addition to an aldosteronoma. Sam and colleagues demonstrated similar results in 342 patients: upwards of 22% were not correctly identified by CT.[135] Most patients with PA and a unilateral adrenal mass can proceed to unilateral adrenalectomy with successful treatment of PA. Patients with bilateral adrenal nodules, as well as those with confounding CT and biochemical evaluations, should undergo bilateral, selective AVS for aldosterone levels to identify lateralization of, and thus the source or sources of, aldosterone secretion.[136]

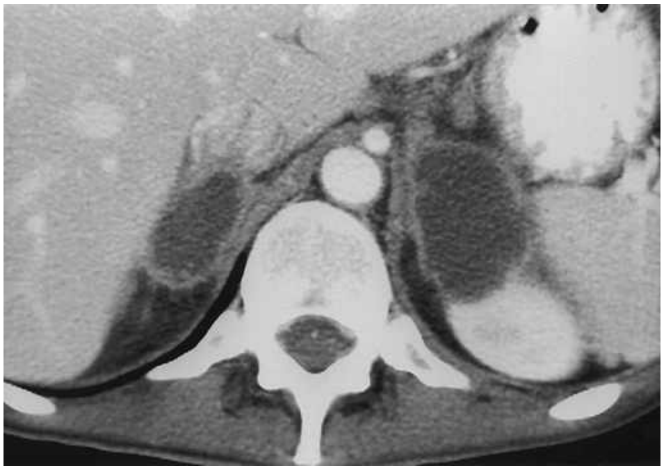

Fig. 92.27 Necrotic metastasis from adenocarcinoma of the lung in a 34-year-old woman. Bilateral adrenal masses with areas of central necrosis are seen on this contrast-enhanced computed tomography examination. (From Dunnick NR, Korobkin M. Imaging of adrenal incidentalomas: current status. *Am J Roentgenol.* 2002;179:559–568.)

Although most cross-sectional studies of patients with PA have used CT, smaller series have suggested that MRI may be able to differentiate APA from IHA.[137] Among 20 patients who underwent MRI, ten (50%) had APA, and ten (50%) had IHA. In the detection of APA, MRI had a sensitivity (70%), specificity (100%), and accuracy (85%) comparable to CT.[138,139] Traditionally, diagnosis of IHA by CT or MRI has been made by excluding the presence of an "adenoma." One CT-based study suggested that diagnosis of hyperplasia can be made by measuring adrenal gland limb width, because adrenal glands were significantly larger in bilateral hyperplasia than in APA or in normal subjects. A sensitivity for identification of IHA of 100% was achieved when a mean limb width exceeded 3 mm and a specificity of 100% when the mean limb width was greater than 5 mm. The authors proposed restricting adrenal venous sampling to situations in which mean adrenal limb width fell between 3 and 5 mm.[132]

Catheterization for venography and AVS can help identify a cause for primary hyperaldosteronism. AVS is usually performed with a percutaneous right transfemoral venous approach. Tandem sheaths are utilized, with one large enough to allow for simultaneous aspiration of iliac venous blood that represents IVC sampling. Shaped catheters are directed into right and left adrenal veins to allow for simultaneous sampling. Aliquots are collected and sent for cortisol and aldosterone assays. If there is doubt about the catheter position, rapid cortisol assay may be performed. Rapid aldosterone assay is not yet available in the United States. Gentle hand injection into the adrenal vein with simultaneous digital subtraction imaging is usually sufficient to confirm successful adrenal venous catheterization. Samples are obtained from both adrenal veins and the iliac venous or IVC sheath. After baseline samples are obtained, adrenal cortical hormonal stimulation with Cortrosyn (0.25 mg) (synthetic analogue

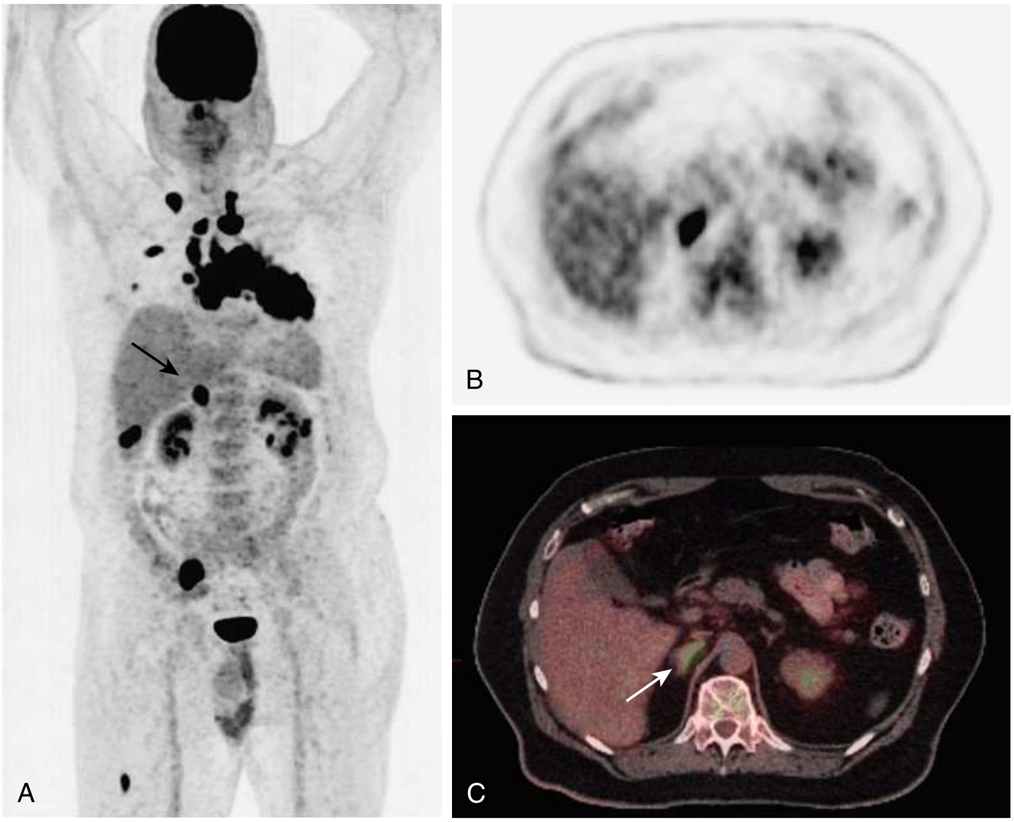

Fig. 92.28 **(^{18}F)-fluorodeoxyglucose (FDG) positron emission tomography/computed tomography (PET/CT) study for staging of lung cancer.** Maximum intensity projection (**A**), axial PET (**B**), and fused PET/CT (**C**) images show thickening of the right adrenal gland *(arrows)* with an increased FDG uptake of similar intensity to the primary left lower lobe tumor. The adrenal maximum standard uptake value (SUV) of 28 compared with the liver background SUV mean of 2.6 is compatible with metastatic disease to the adrenal gland, in the presence of widespread metastases. (From Wong KK, Arabi M, Zerizer I, et al. Role of PET/CT in adrenal and neuroendocrine tumors: FDG and non-FDG tracers. *Nuc Med Comm.* 2011;32:764–781.)

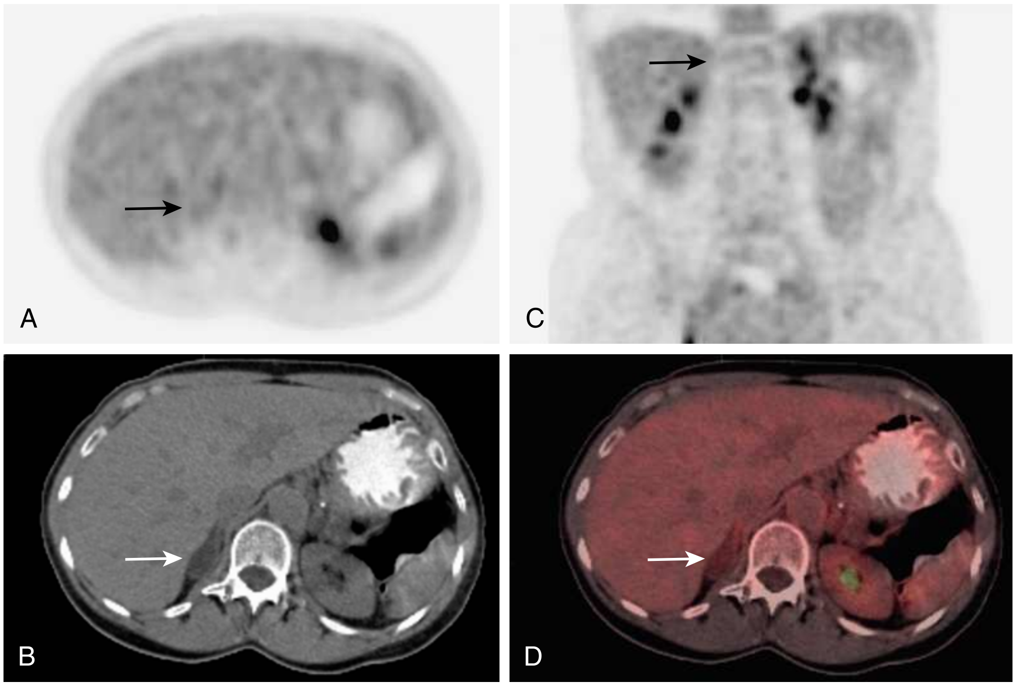

Fig. 92.29 **(^{18}F)-fluorodeoxyglucose positron emission tomography/computed tomography (PET/CT) study in a 74-year-old man with lung cancer.** Restaging PET/CT images show a 3-cm right adrenal lesion *(arrows)* with maximum standard uptake value (SUV) of 4.4 as compared with the normal liver background SUV mean of 2.4 with lesion/liver maximum SUV ratio of 1.5, meeting the metabolic criteria for adrenal nonadenoma. However, this lesion displayed low CT attenuation with <10 Hounsfield units and was stable at 2 years imaging follow-up compatible with an adrenocortical adenoma. There is overlap in SUV uptake of benign versus malignant adrenal lesions. (From Wong KK, Arabi M, Bou-Assaly W, et al. Evaluation of incidentally discovered adrenal masses with PET and PET/CT. *Eur J Radiol.* 2012;81:441–450.)

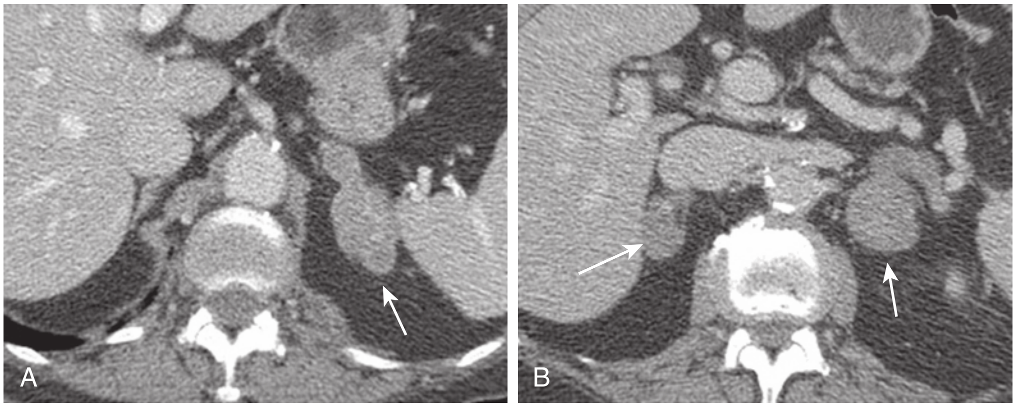

Fig. 92.30 ACTH-independent macronodular adrenal hyperplasia. A and B show large nodules bilaterally superimposed on markedly thickened limbs. *ACTH*, Adrenocorticotropic hormone.

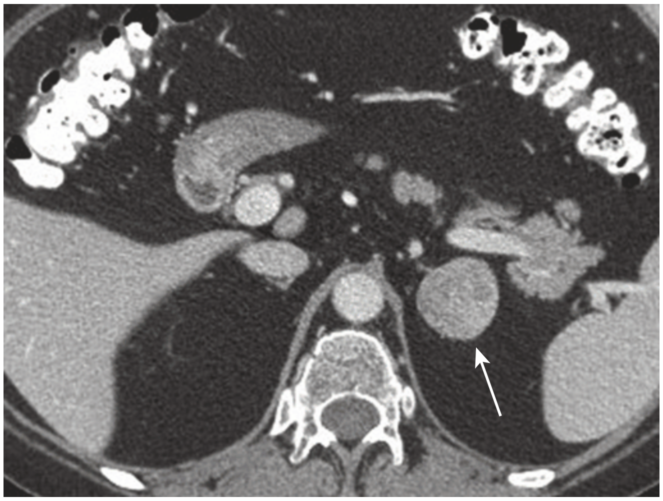

Fig. 92.31 Adrenal adenoma causing Cushing syndrome. Homogeneous 4-cm left adrenal mass *(arrow)* has a nonspecific computed tomography appearance. *L*, Left. (From Korobkin M, Francis I, Kloos R, et al. The incidental adrenal mass. *RCNA*. 1996;34:1037–1054.)

of ACTH) is initiated, followed by poststimulation sampling after 5 to 30 minutes. After sampling, catheters and sheaths are removed, and hemostasis is achieved by manual groin pressure, and patients are discharged to home after a brief recovery period. Potential complications of AVS include venous infarction of the adrenal gland and adrenal hemorrhage. These complications may cause pain, fever, and damage to adrenal gland function. Note that performance of AVS can be quite technically challenging, and success depends upon operator skill and experience.[140,141]

Interpretation of Adrenal Vein Sampling assays in Primary Hyperaldosteronism

Determination of aldosterone and cortisol concentrations in adrenal venous blood can accurately localize the site of aldosterone excess and thereby distinguish unilateral from bilateral adrenal disease. Cortisol assays provide a means of compensating for differences in hormone concentration resulting from catheter placement and dilution of adrenal venous effluent. Calculation of the selectivity index (adrenal vein cortisol/IVC cortisol) is performed for adrenal venous and IVC sampling obtained before and after Cortrosyn stimulation. Adequate sampling is reflected by a selectivity index of greater than 2 before stimulation and greater than 5 after stimulation.

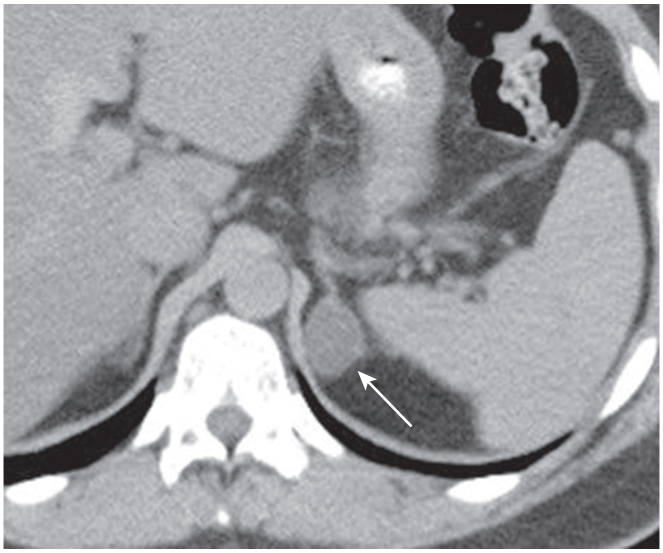

Fig. 92.32 Computed tomography demonstration of a 1-cm aldosterone-producing left adrenal adenoma.

The sensitivity index is calculated using the ratio of aldosterone/cortisol (A/C) concentrations from each aliquot. Right and left adrenal vein and IVC samples before stimulation are compared. The A/C ratio of the side with the higher value is used as a numerator, and that of the lesser value as the denominator and a new ratio is calculated, comparing the two adrenal glands. This value is the sensitivity index. If this value is greater than 3 prestimulation or greater than 5 poststimulation, unilateral hypersecretion is confirmed, provided that the selectivity index previously calculated indicates adequate and valid sampling. Added confidence is present when the A/C ratio of the nondominant side is less than the A/C ratio of the IVC obtained in the concomitant sampling. This indicates "suppression" of aldosterone secretion by the nondominant side.

PA guidelines recommend adrenalectomy that can cure cases of hypertension and hypokalemia when the etiology is secondary to unilateral adrenal secretory masses.[142] Adrenal CT and MRI remain the mainstay with AVS, with care required for the occasional ACC. False positive imaging findings (nonsecretory adenoma) and false negatives (unilateral adrenal hyperplasia) can both occur. Currently, there is a need for functional imaging to guide management of secretory adrenal tumors.[143]

Functional Imaging in Primary Hyperaldosteronism

NP-59 adrenocortical scintigraphy has been well established for localization of functional adrenal masses for both Conn syndrome and PA, although it currently has limited availability in North America. For PA, the addition of dexamethasone suppression of pituitary ACTH secretion leads to decreased accumulation of radiocholesterol by the inner adrenal cortex and allows accurate depiction of aldosterone producing adenoma.[2] NP-59 imaging has been improved with combined SPECT/CT imaging technique for lateralizing the source of hyperaldosteronism and distinguishing adenoma from bilateral adrenal hyperplasia.[144,145] In a single-site retrospective study in 81 patients, NP-59 scintigraphy was reported to have sensitivity of greater than 83% and a positive predictive value of greater than 92%.[146]

An alternative to adrenocortical imaging has been development of a radiotracer, ^{11}C-metomidate (MTO), a ligand of CYP11B1 and CYP11B2, which has a potential role in the characterization of adrenocortical adenomas and for lateralization of functional adenomas.[147] ^{11}C-MTO–PET can aid in differentiating tumors of adrenocortical origin (including nonhypersecreting and hypersecreting cortical adenomas, ACCs, and macronodular hyperplasia) from nonadrenocortical tumors (benign and malignant pheochromocytoma, and metastases to the adrenal),[148,149] with a sensitivity of 89% and a specificity of 96% reported in 212 patients.[150] ^{11}C-MTO–PET has been successfully used for localizing unilateral APAs when AVS is ambiguous or cannot be performed and using dexamethasone suppression can depict PA due to adrenal adenoma.[151] Compared with AVS, ^{11}C-MTO–PET had a reported sensitivity of 76% and specificity of 87% for aldosteronoma.[152] Another small study of 15 patients with PA confirmed ^{11}C-MTO–PET as a useful adjunct to AVS and CT.[153] Radioiodine labeling of metomidate (^{123}I-MTO) allows SPECT/CT imaging of hypersecreting adrenocortical masses with an efficacy similar to PET. A fluorinated version of a CYP11B1/2 radiotracer ligand promises wider availability of PET imaging.[154]

A novel approach to hyperaldosteronism is the use of chemokine receptor 4 (CXCR4) PET imaging, with aldosterone-producing adrenal adenoma demonstrated to have intense uptake on ^{68}Ga-pentixafor–PET imaging.[155] In 36 patients with PA, Heinze et al. reported that ^{68}Ga-pentixafor–PET imaging had 100% sensitivity, 78.6% specificity, and 92.3% accuracy for APA.[156] They found that CXCR4 was expressed in aldosterone-producing tumors but, importantly, not in nonfunctioning adenomas. In nine patients with hyperaldosteronism, ^{68}Ga-pentixafor PET findings were able to lateralize the side of disease, which is important for predicting surgical cure.[157]

KEY POINTS

- Both benign and malignant adrenal lesions can have varied appearances, some with specific diagnostic characteristics depending on the lesion and/or the imaging modality chosen.
- Correlation with patient history can be helpful in narrowing down differential diagnoses.
- Functional imaging can help delineate pathology type and location.
- Functional status (hormone production) is difficult to determine with imaging.
- Although functional status can be difficult to determine in certain pathologies, the presence of hormones on AVS can help with diagnosis and quantifying severity of disease.

SUMMARY

The challenge of adrenal imaging lies in understanding the unique and complementary interplay of the anatomic- and functionally based imaging modalities. The presence of an adrenal mass does not invariably confirm abnormal adrenal function; nor does the presence of normal adrenal anatomy necessarily exclude abnormal adrenal function. Adrenal physiology and pathophysiology must be considered so that appropriate follow-up studies are properly performed and correctly interpreted. Regardless of whether the imaging modality is anatomic- or functionally based, the imaging approach to a given patient must be flexible and at times specifically tailored for each particular disease entity. When conducted in the proper clinical setting and sequence (reasonable suspicion based on clinical features and biochemical studies), CT, MRI, catheter-directed hormone sampling, and radiopharmaceutical imaging using hybrid PET/CT and/or SPECT/CT can be expected to have their greatest clinical utility and diagnostic success.

BRIEF HISTORICAL PERSPECTIVE: THE CHANGING SPECTRUM OF ADRENAL INSUFFICIENCY ETIOLOGY

Adrenal insufficiency (AI) is defined by inadequate secretion of cortisol and/or aldosterone by the adrenal cortex to maintain homeostasis. Bartolomeo Eustachi, in 1563, first recognized the adrenal glands as organs distinct from the kidneys.[1] Addison disease, eponymously named after Thomas Addison, refers to primary AI (PAI), that is, resulting from direct adrenal pathology. Thomas Addison described many diseases through correlation of clinical presentation with autopsy examination. Addison's description of AI remains as accurate today as it was in 1855: "anaemia, general languor and debility, remarkable weakness of the heart's action, irritability of the stomach, and a peculiar change of colour in the skin." Addison was studying pernicious anemia when he discovered adrenal pathology: tuberculous adrenal lesions in some patients with tuberculosis and adrenal atrophy in others, some of which had vitiligo and pernicious anemia. Of 11 patients described, five had bilateral adrenal tuberculosis, one had unilateral adrenal tuberculosis, three had carcinomatous adrenal involvement, one had adrenal hemorrhage, and one showed atrophy and fibrosis. Addison's findings were quickly confirmed by Brown-Sequard,[2] who verified Addison's hypothesis by showing that, in several laboratory animals, bilateral adrenalectomy was uniformly fatal. The clinical syndrome was named after Addison by Trousseau.[3] Osler attempted unsuccessfully to treat a young patient with Addison disease, employing a glycerine extract of fresh porcine adrenals given orally,[4-6] and isolated and characterized cortisone and cortisol in the 1930s, and Sarett devised a partial synthesis for cortisone from deoxycholic acid in 1945. The clinical effects of cortisone soon were made apparent by the work of Hench and coworkers[7] in the treatment of rheumatoid arthritis and by Thorn and Forsham[8] in the treatment of AI. Cushing largely clarified the role of the pituitary gland in regulating adrenal function, and Harris[9] in the 1940s clarified the role of the hypothalamus in regulating pituitary function via the hypothalamo-hypophyseal portal circulation. Adrenocorticotropic hormone (ACTH) was isolated and characterized by Li,[10] and corticotrophin-releasing hormone (CRH), in turn, was characterized by Vale[11]. Sampson, in 1961, first recognized the syndrome of acute AI in a surgical patient who had atrophic adrenal glands secondary to longstanding glucocorticoid treatment.

The etiological spectrum of AI has evolved considerably. The majority of cases now result from the use of supraphysiologic, anti-inflammatory doses of glucocorticoids in the many diseases that respond well. Among children, genetic disorders (e.g., developmental pituitary defects or congenital adrenal hyperplasia [CAH]) are frequent causes of AI, as well as childhood cerebral tumors or their treatment, now often successful. Autoimmunity is a common cause of PAI, but newer drugs, particularly those used in oncology to increase immune activity, the CTLA-4, PD-1, and PD-L1 antibodies, may produce hypophysitis/secondary AI (SAI).[12] In addition, opioids cause SAI, especially in high cumulative doses.[13] Human immunodeficiency virus infection of the adrenals or attendant adrenal mycotic infections and/or antifungal inhibition of adrenal steroidogenesis may lead to AI, an outcome less frequent with antiretroviral therapies.[14] Observations of salutory pressor effects of hydrocortisone in septic shock and their possible relation to impaired responsiveness of cortisol to ACTH stimulation have led to the notion of relative AI, now referred to as critical illness-related corticosteroid insufficiency (CIRCI), an area that requires better endocrine definition.[15] These observations highlight the importance of considering clinical context in AI differential diagnosis and considering newer causes as they appear in the community.

EPIDEMIOLOGY OF ADRENAL INSUFFICIENCY

Primary AI has an annual incidence of 4 to 6 cases per million and a prevalence of 100 to 220 cases per million, which may be increasing SAI is considered to be twice as common as PAI. The exact prevalence of exogenous adrenal suppression is not known. Adrenal crises are more frequent in PAI than in SAI (estimated in one study to be 5.2 and 3.6 adrenal crisis (AC) per 100 person-years (PY), respectively).[16]

PATHOGENESIS OF ADRENAL INSUFFICIENCY

The hypothalamic-pituitary-adrenal (HPA) axis comprises a classic negative feedback loop (see Chapter 132).

Many pathological processes can lead to loss of adrenal or hypothalamic-pituitary function, and each of these have intrinsic implications.[7] Endocrine consequences arise from loss of adrenal hormones, most importantly cortisol and aldosterone. Although not routinely replaced, there is a loss of production of adrenal androgens, DHEA(-S) and androstenedione, which may result in reduced androgen-dependent hair, especially in females, where adrenal androgens represent approximately 50% of circulating androgens. A lack of adrenal cortisol secretion markedly reduces adrenomedullary epinephrine secretion through depriving the phenylethanolamine-N-methyltransferase enzyme of its stimulatory drive; the extent of practical pathological implications is unclear, but may theoretically include a blunted response to hypoglycemia and an altered sympathoadrenal (epinephrine) response to stress. Low plasma epinephrine and metanephrine levels and low urinary epinephrine excretion can be observed CAH patients with 21-hydroxylase deficiency, which, when severe, can result in frequent hospitalizations for hypoglycemia and hypotension.[18]

Primary AI, most often autoimmune where tuberculosis is not endemic, results in loss of glomerulosa cells and fasciculata cells, leading to lack of aldosterone and cortisol. Typical sequential hormone deficits include increased serum renin, reduced serum aldosterone, and increased serum ACTH, followed by reduced serum cortisol.[19] Usually, AI patients are diagnosed in the most symptomatic low-cortisol state. Isolated loss of cortisol secretion may be seen in autoimmune disease but more commonly follows other insults such as adrenal hemorrhage.

In general, PAI involves deficiency of aldosterone and cortisol, as well as ACTH hypersecretion. The loss of aldosterone secretion and ACTH hypersecretion are not seen in SAI; hence, only PAI patients typically have hyperkalemia from aldosterone deficiency and hyperpigmentation from ACTH and other proopiomelanocortin (POMC) peptides such as α-MSH that have melanocyte-stimulating properties via melanocortin-1 receptors.

SAI is caused by deficits in ACTH secretion, because of loss of hypothalamic CRH production or direct pituitary pathology. The result is low cortisol secretion and normal or low serum ACTH concentration. Common pituitary/hypothalamic pathologies are pituitary adenomas, suprasellar or hypothalamic tumors such as craniopharyngioma, inflammatory disease of either organ, or iatrogenic damage from surgery or radiotherapy. These pathologies may have distinct clinical features or influence the rate of onset of AI. Hypothalamic-pituitary lesions produce cortisol deficiency, but aldosterone is normal because it is regulated primarily by the renin-angiotensin system and serum potassium.

The actions and mechanisms of action of glucocorticoids and mineralocorticoids are discussed in detail elsewhere in this text (see Chapters 88-89). Cortisol has protean effects, including: immunomodulation with an initial immune enhancing effect on infection or injury followed by immune response containment to prevent healthy tissue damage; substrate mobilization increasing circulating glucose, fatty acids, and amino acids to maintain nutrition of key tissues in times of stress or starvation; cardiovascular support acting to maintain cardiac contractility; modulation of the vascular response to the β-adrenoceptor agonists; and neurocognitive effects so as to enhance attention and awareness, thereby facilitating an optimum response to stress. Aldosterone regulates exchange of sodium, potassium, and hydrogen ions at the renal tubule, the gut, and the salivary glands, promoting sodium reabsorption at the expense of potassium and hydrogen excretion.

CLINICAL FEATURES OF ADRENAL INSUFFICIENCY

Primary adrenal glucocorticoid insufficiency is manifest by weakness, fatigue, nausea, loss of appetite, vomiting, and weight loss, ACTH-mediated hyperpigmentation (typically of the palmar creases, scars, knuckles, and oral mucosa) (Fig. 93.1), hypotension, often postural, with tachycardia, because of reduced stroke volume, and decreased peripheral vascular resistance. Some cases may present with hypoglycemia. Depressed mood and reduced ability to concentrate are common. Back and leg pains may develop. Concomitant mineralocorticoid deficiency is manifest by hyponatremia, hyperkalemia, and metabolic acidosis. Hyperpigmentation is evident in palmar creases, scars, knuckles, and oral mucosa.

In SAI, isolated glucocorticoid insufficiency lead to the effects listed earlier for PAI. Although hyperkalemia does not occur, hyponatremia develops because of arginine vasopressin antidiuretic hormone ADH-mediated water retention as a physiological response to hypotension/volume depletion with exacerbation from the vasopressin-stimulating effect of nausea.

Clinical features of AI may arise acutely or chronically. The insidious, nonspecific evolution of symptoms in most patients leads to delayed diagnosis, sometimes in excess of 1 year. Adrenal crisis may supervene before diagnosis of AI, with an attendant mortality risk. Prediagnosis considerations sometimes include mood disorders, anorexia nervosa, or malignancy.

Cortisol deficiency leads to derepression of inflammatory cytokines, leading to increased body temperature with various patterns of pyrexia and the sickness syndrome.[20] In females, decreased axillary and pubic hair, loss of libido because of loss of adrenal androgens, and amenorrhea may occur because of weight loss.

Routine laboratory tests may show hyponatremia, mild metabolic acidosis, and prerenal azotemia, but hyperkalemia (in PAI) is more specific and facilitates diagnosis. Although hyperkalemia is typical, many patients have normal potassium at least in part because of frequent vomiting. Less common laboratory abnormalities include hypoglycemia (more frequent in children) and hypercalcemia. Hematologic abnormalities associated with AI include normochromic, normocytic anemia, relative lymphocytosis, and eosinophilia.

Adrenal crisis is a medical emergency with generally severe features of AI and an acute deterioration in health associated with absolute hypotension (systolic blood pressure <100 mm Hg) or relative hypotension (systolic blood pressure at least 20 mmHg lower than usual); features resolve within 1 to 2 hours after parenteral glucocorticoid administration (i.e., a marked resolution of hypotension within 1 hour and improvement in clinical symptoms over a period of 2 hours).[20]

KEY POINTS

- Adrenal insufficiency (AI) is uncommon and arises from lesions of the adrenal gland, pituitary, or hypothalamus.
- Pathologies such as autoimmune disease, tumors, surgery, genetic disorders, drugs, or exogenous glucocorticoids account for the majority of cases.
- This diversity of causes implies that AI may develop in any clinical setting. Relatively nonspecific clinical presentations in unfamiliar settings often leads to hazardous diagnostic delay.

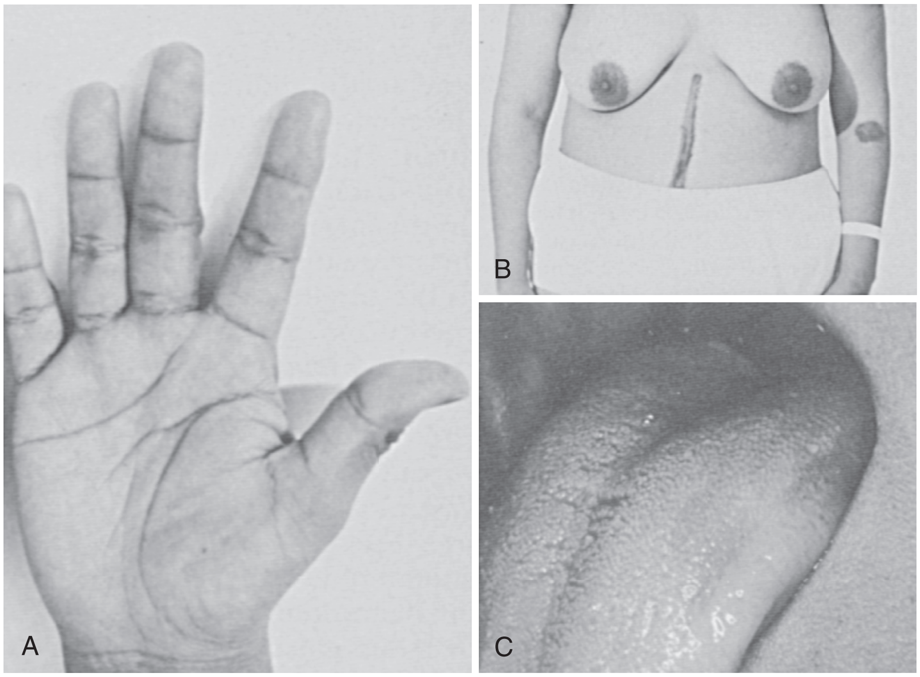

Fig. 93.1 Hyperpigmented hand (A), scar and areolae (B), and buccal mucosa (C). (From Loriaux L, Cutler Jr G. Disease of the adrenal gland. In: Kohler P, ed. *Clinical Endocrinology*. New York: Churchill-Livingstone; 1986:211.)

ETIOLOGY

Primary Adrenal Insufficiency

Primary AI diverse etiologies, as listed in Table 93.1.

Autoimmune Adrenal Insufficiency. In high-income countries, 80% to 90% of patients with PAI have autoimmune adrenalitis, which can be isolated, or seen as part of an autoimmune polyendocrine syndrome, with autoimmune thyroid disease the most frequent association.[21] Autoimmune Addison disease is associated with antibodies to adrenal biosynthetic enzymes, most often to the 21-hydroxylase enzyme, detectable in the serum of more than 90% of recent-onset patients. The cumulative risk of developing autoimmune Addison disease in the presence of 21-hydoxylase antibodies was 39%, somewhat higher in males, with median follow-up of 10 years.

Autoimmune polyendocrine syndrome type II (APS-II). Approximately 50% of patients with Addison disease exhibit an autoimmune polyendocrinopathy. APS-II was previously defined as autoimmune AI combined with either autoimmune thyroid disease (Schmidt syndrome) and/or type 1 diabetes mellitus (T1DM). A wider definition is now applied incorporating numerous other organ-specific autoimmune diseases such as vitiligo (Fig. 93.2), alopecia, autoimmune gastritis with iron and vitamin B12 deficiency, premature ovarian insufficiency, celiac disease, and, more rarely, myasthenia gravis, central diabetes insipidus, and lymphocytic hypophysitis (Table 93.2).[22] APS-II shows familial aggregation, with a wide variation in number and type of components between family members. Autoimmune disease presents mainly in the third or fourth decade, with a female-to-male ratio of 1 to 1.8:1. APS-II is the most common immunoendocrinopathy, with an estimated prevalence of 5 to 14 cases per 100,000 population.

Autoimmune Addison disease is polygenic in origin. The strongest genetic association is with specific haplotypes of human leukocyte antigen class 2 (HLA class II), including DR3-DQ2 and DR4*0404-DQ8 and the cytotoxic T cell antigen (CTLA-4).[22] Other genes associated with autoimmune Addison disease include *BACH2* and *PTPN22*. Many of these genetic associations overlap with related disease such Hashimoto thyroiditis, Graves disease, T1DM, and celiac disease, reflecting the high prevalence of APS-II.

The environmental factors precipitating a break in tolerance to the adrenal cortex are largely unknown. Herpes virus infection has been suggested as a potential factor, as the virus may infect the adrenal and lead to adrenal dysfunction.[23]

Autoimmune polyendocrine syndrome type I (APS-I) is also known as autoimmune polyendocrinopathy, mucocutaneous candidiasis, and ectodermal dystrophy. This is a rare, monogenic, autosomal recessive disease that is most prevalent in certain stable populations, including Finns and Persian Jews. The gene that causes this syndrome is located on chromosome 21q22 and encodes a protein known as autoimmune regulator (molecular pathogenesis covered in Chapter 132). To date, more than 120 mutations have been reported, some of which are dominant and give rise to milder phenotypes.

The typical presentation is persistent *Candida* infection of the skin and mucous membranes, without severe systemic infection, in childhood, followed by hypoparathyroidism and then adrenal failure.[24] Almost all patients display autoantibodies against interferon omega and alpha.[25]

X-linked polyendocrinopathy immune dysfunction and diarrhea is a rare inborn error of immune regulation that presents as neonatal diabetes and is often fatal. The disorder is also known as X-linked autoimmunity and allergic dysregulation and immune dysfunction, polyendocrinopathy, and enteropathy, X-linked (IPEX). IPEX is caused by mutations in *FOXP3*, which is a critical determinant of CD4+ and CD25+ T regulatory cell development and function. See Chapter 132.

Infectious Adrenalitis. Infectious diseases represent the most common cause of primary adrenal failure worldwide, with generalized tuberculosis being the most frequent single cause.[23] On abdominal computed tomography (CT), an enlarged adrenal with necrotic areas

TABLE 93.1 Causes of Primary Adrenal Insufficiency

Diagnosis	Pathogenesis
Autoimmune Adrenal Insufficiency	
Autoimmune Addison disease	Antibodies against 21-hydroxylase most common, other steroidogenic enzymes such as 17α-hydroxylase, side-chain cleavage enzyme, and *CTLA-4*
APS type I or APCED	Mutations in *AIRE* (autoimmune regulator 1)
APS type II	Multiple genes including *HLA DR3/4, DRBI, DQAI, DQBI, BACH2,* and *CTLA-4*
X-linked polyendocrinopathy	*FOXP3*
Infectious	
Tuberculosis	Tuberculous adrenalitis
Systemic fungal infections	Histoplasmosis, cryptococcosis, blastomycosis
AIDS	Opportunistic infection with CMV, bacteria, protozoa, Kaposi sarcoma
Adrenal infiltration	Metastases, lymphoma, sarcoidosis, amyloidosis, hemochromatosis, histiocytosis (Erdheim–Chester disease)
Bilateral adrenalectomy	Indications include ACTH-independent Cushing syndrome or persistent ACTH-dependent Cushing syndrome, bilateral pheochromocytoma
Medication-induced	Mitotane, ketoconazole, and etomidate
Bilateral adrenal hemorrhage	Meningococcal meningitis, antiphospholipid syndrome, anticoagulation therapy, coagulation disorder, septic shock
Genetic Disorders	
Congenital adrenal hyperplasia	Mutations in the genes encoding 21-hydroxylase (*CYP21A2*), 11β-hydroxylase (*CYB11B1*), 17-hydroxylase (*CYP17A1*), or 3β-hydroxysteroid dehydrogense type 2 (*HSD3B2*), PORD
Adrenoleukodystrophy/adrenomyeloneuropathy	Excessive accumulation of very long chain fatty acids in brain and adrenal cortex; mutations in the *ABCD-1* gene
Familial Glucocorticoid Deficiency	
Type 1	Melanocortin 2 receptor (*MC2R*) mutation
Type 2	Melanocortin 2 accessory protein (*MRAP*) gene mutation
Type 3	Genetic origin unknown
Congenital lipoid adrenal hyperplasia	Mutations in the gene encode the steroidogenic acute regulatory protein (*StAR*)
Triple A syndrome	Mutations in *AAAS* encoding ALADIN
Congenital adrenal hypoplasia	Mutation in the orphan nuclear receptor DAX-I (*NROB1*), *SF-I*, or other unidentified genes

ACTH, Adrenocorticotropic hormone; *AIDS*, acquired immunodeficiency syndrome; *APCED*, autoimmune polyendocrinopathy, mucocutaneous candidiasis, and ectodermal dystrophy; *APS*, autoimmune polyendocrine syndrome; *CMV*, cytomegalovirus; *PORD,* cytochrome P450 oxidoreductase deficiency.

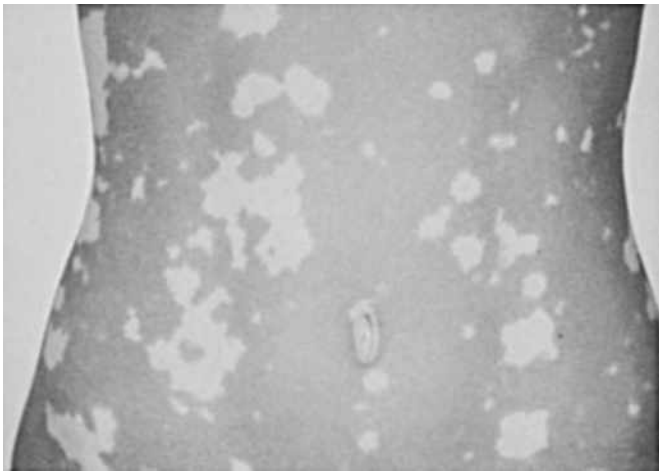

Fig. 93.2 Vitiligo. (From Loriaux L, Cutler Jr G. Disease of the adrenal gland. In: Kohler P, ed. *Clinical Endocrinology*. New York: Churchill-Livingstone; 1986:211.)

can be seen in the early stages, while later stages are characterized by adrenal calcification (Fig. 93.3). All the clinically important fungi except *Candida* can also cause AI. The most common is histoplasmosis, which is particularly prominent in the Ohio and Tennessee River Valleys and along the Piedmont Plateau of the Middle Atlantic States, as well as in Southern India. South American blastomycosis is the next most common fungal cause of AI, followed by North American blastomycosis, coccidioidomycosis, and cryptococcosis, although all are rare causes of adrenal destruction. The pathophysiology of this process is much like tuberculosis, with early adrenal enlargement, healing, calcification, and adrenal atrophy or resumption of normal volume.

Acquired immunodeficiency syndrome (AIDS) can be associated with AI in its late stages. The adrenals are involved with infection or tumor in well over half of autopsy cases, although less than 50% of the adrenal gland is destroyed in 97% of cases. This explains the rarity of overt symptoms. Cytomegalovirus infection of the adrenal glands is common in AIDS, as is infection with *Mycobacterium avium intracellulare* and fungi that can colonize and destroy the adrenal glands. The plasma cortisol response to ACTH administration, however, is abnormal in only 10% to 15% of affected cases.

Medications and Adrenal Insufficiency. Although fluconazole, ketoconazole, phenytoin sodium, rifampicin, and barbiturates may precipitate AI, they are rarely the cause, except in the case of high-dose azole antifungals, where the intention is to inhibit adrenal steroidogenesis to treat endogenous Cushing syndrome. One exception is the anesthetic agent etomidate, an inhibitor of the adrenal steroidogenic enzyme 11β-hydroxylase, which can induce AI, with an attendant increase in mortality, as initially noted in trauma victims.[26]

Adrenal Infiltration. Metastases to the adrenal gland can be found in as many as 60% of patients with disseminated breast or lung cancer

TABLE 93.2 **Features of Autoimmune Polyendocrine Syndrome (APS)-I, APS-II, and X-Linked Polyendocrinopathy**

Features	APS-I	APS-II	X-Linked Polyendocrinopathy Immune Dysfunction and Diarrhea
Prevalence	Rare	Common	Very rare
Time of onset	Infancy	Adulthood	Neonatal period
Genetic and inheritance	Monogenic, *AIRE*	Polygenic	*FOXP2*, X-linked
Immunodeficiency	Asplenism, susceptibility to candidiasis	None	Overwhelming autoimmunity Loss of regulatory T-cells
Adrenal insufficiency	60%–70%	40%–50%	+
Diabetes mellitus	<20%	50%–60%	80%
Autoimmune thyroid disease	10%	70%–75%	+
Premature ovarian failure		Up to 21%	
Hypoparathyroidism	80%–85%	0%–5%	–
Mucocutaneous candidiasis	70%–80%	Nil	–
Male hypogonadism	12%	Rare	–
Hypopituitarism	0%–2%	<0.1%	–
Chronic active hepatitis	+	Rare	+
Pernicious anemia	+	0.1%–10%	–
Skin manifestation	Vitiligo, alopecia 10%–15%	Vitiligo, 5%–10%	Eczema, psoriasis, or atopic dermatitis
Gastrointestinal	Diarrhea, constipation	Celiac, 4%–9%	Enteropathy, malabsorption

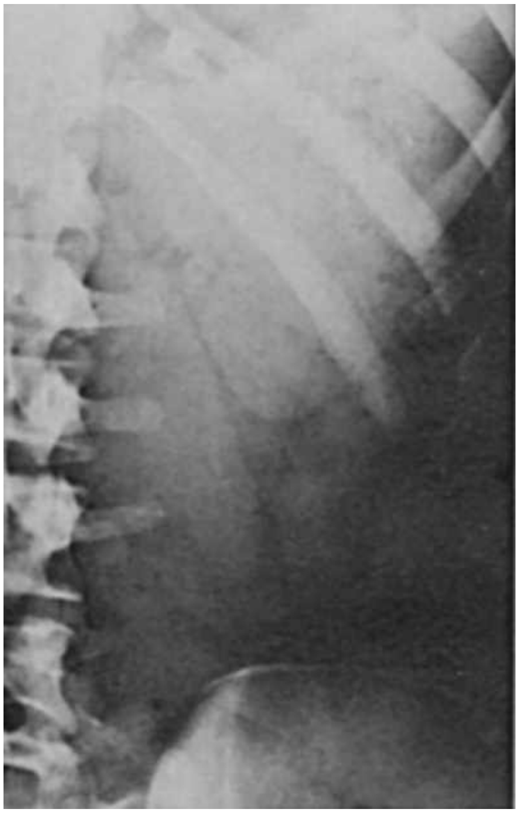

Fig. 93.3 Adrenal calcification on "flat plate" of the abdomen. (From Loriaux L, Cutler Jr G. Disease of the adrenal gland. In: Kohler P, ed. *Clinical Endocrinology*. New York: Churchill-Livingstone; 1986:211.)

and are often bilateral. Although generally considered uncommon on clinical grounds, PAI was reported in 12.4% of patients with bilateral adrenal metastases, and in 20% of patients with bilateral metastases and adrenal mass size greater than 4 cm. Tumors that are commonly associated with AI are cancers of the lung, kidney, stomach, colon, and breast, as well as melanoma and lymphoma.

A further occasional cause of adrenal failure is amyloidosis,[27] which is often underdiagnosed and masked by other clinical manifestations of the disease. Likewise, severe untreated hemochromatosis has been reported to cause AI, but is now rarely seen. In addition, Erdheim–Chester disease can cause PAI as a result of adrenal infiltration.

Bilateral Adrenalectomy. This procedure may be used to treat persistent ACTH-dependent Cushing disease or bilateral micronodular or macronodular hyperplasia with ACTH-independent Cushing syndrome, or for bilateral pheochromocytomas, and results in abrupt-onset PAI.

Adrenal Hemorrhage. With the advent of the abdominal CT, adrenal hemorrhage is recognized more frequently as a cause of AI. Early reports of adrenal hemorrhage and its consequences followed cases of meningococcal septicemia, particularly in children and young adults (Waterhouse–Friedrichsen syndrome). The usual setting is a stressed individual anticoagulated for the prevention of pulmonary emboli or other thrombotic phenomena, frequently after surgery. Other scenarios include trauma, hemorrhagic shock, sepsis, extensive burns, or during adrenal vein sampling for investigation of primary aldosteronism. Adrenal hemorrhage may be a manifestation of the antiphospholipid syndrome. Typically, the patient will complain of back pain, which is followed in a few days by the acute onset of the first signs and symptoms of AI, without the usual hyperpigmentation. These patients rarely recover adrenal function.

Genetic Disorders. *CAH* is a family of inborn errors of steroidogenesis, each characterized by a specific enzyme deficiency that leads to a range of adrenal hormone abnormalities depending on the specific enzyme affected. Adrenal steroid abnormalities include impairment of cortisol and aldosterone synthesis from the adrenal, excess or reduced sex steroid synthesis, and excess mineralocorticoid precursors. These autosomal recessive diseases involve impaired enzymatic function arising from gene mutations affecting are the cytochrome P450 enzymes 21-hydroxylase, 11β-hydroxylase, and 3β-hydroxylase dehydrogenase and, less often, 17α-hydroxylase/17,20-lyase, cholesterol desmolase, and the more recently described mutations of P450 oxidoreductase, the electron donor for all CYP450 enzymes.[28] Over 95% of cases of CAH have 21-hydroxylase deficiency with varying degrees of deficiency of cortisol and aldosterone synthesis, elevations of ACTH, and consequent excess adrenal androgens. 21-hydroxylase deficiency is the most common cause of AI in children. Detailed descriptions of the CAH variants and other genetic forms of altered adrenal steroidogenesis are found in Chapter 94.

Congenital lipoid adrenal hyperplasia is a rare form of adrenal steroidogenic defect and is inherited in an autosomal recessive pattern. The disease results from mutations in the gene on chromosome 8p11 that encodes the steroidogenic acute regulatory protein, which regulates cholesterol uptake into the mitochondria in readiness for conversion to pregnenolone, the first step of steroidogenesis.[29]

Adrenoleukodystrophy (ALD) and *adrenomyeloneuropathy (AMN)* are two clinical presentations of the same disorder that may exhibit a broad phenotype. ALD, also known as *Brown Schilder disease* (*brown* being an adjective describing the hyperpigmentation of the skin) or *sudanophilic leukodystrophy,* is typically a disease of children characterized by rapidly progressive central demyelination that eventuates in seizures, dementia, cortical blindness, coma, and death, usually before puberty. However, clinical manifestations can be highly variable, and long survival may occur. Adrenomyeloneuropathy is a disease of young adults that is characterized by a slowly progressive mixed motor and sensory peripheral neuropathy associated with an upper motor neuropathy, leading to an ascending spastic paraparesis. Both forms are associated with progressive failure of steroid-secreting cells leading to adrenal and gonadal failure, but adrenal failure may occur in isolation. Usually ALD is an X-linked disorder, but it may be underrecognized as a cause of adrenal failure. In one large series, it accounted for a significant proportion (8%) of young adult males believed to have autoimmune Addison disease.[30] The metabolic marker for these diseases is an elevated circulating level of very long chain fatty acids (VLCFAs), C26 and greater in length, that rises in response to the primary abnormality, which is a peroxisomal defect in VLCFA metabolism. Peroxisomes are small, intracytoplasmic, membrane-enclosed bodies that contain the enzyme pathways for a number of metabolic and detoxification processes. The gene underlying ALD, identified in 1993 on chromosome Xq28, encodes a half-transporter of the adenosine triphosphate (ATP)-binding cassette membrane transporter class. The protein includes six transmembrane domains and an ATP-binding site and probably functions as a heterodimer with another half-transporter to regulate the uptake of VLCFA into peroxisomes. Many missense, nonsense, and splicing defects in the *ALD* gene have been described, and accumulation of VLCFA in the adrenals seems to be the pathogenic mechanism, although the neuronal pathogenic process may differ. Several treatments have been tried, including Lorenzo's oil containing a mixture of oleic and erucic fatty acids, but only autologous bone marrow transplantation appears to be effective.

Familial glucocorticoid deficiency (FGD) is an autosomal recessive syndrome characterized by cortisol deficiency despite high plasma ACTH and a preserved renin-aldosterone axis.[31] There is considerable phenotypic variation. Usually, patients present in early childhood with clinical AI and undetectable circulating cortisol, although some pass unrecognized until later childhood, and the diagnosis is then made after an ACTH stimulation test. Children tend to be tall for unknown reasons. Patients tend to be highly resistant to glucocorticoid suppression of hyperpigmentation, perhaps as a result of impaired short-loop ACTH feedback. The first molecular abnormality demonstrated was a mutation of the gene encoding ACTH receptor, located on chromosome 18p11, although it is now known that these cases, known as FGD type 1, represent only some 25% of cases of FGD. FGD type 2 is caused by a mutation of the chromosome 21 gene encoding the melanocortin 2 receptor accessory protein. This accounts for approximately 20% of all FGD cases, implying that approximately half of all FGD cases result from other genes. Two additional causative genetic mutations involving minichromosome maintenance-deficient 4 homolog, nicotinamide nucleotide transhydrogenase, and thioredoxin reductase 2 have been identified in FDG cohorts.

Triple A syndrome (Allgrove syndrome) is the association of alacrima, achalasia, and Addison disease. It is associated with a variety of progressive motor, sensory, and autonomic neurologic defects plus mineralocorticoid insufficiency. This recessive condition results from abnormalities in *AAAS* on chromosome 12q13, which encodes a putative nuclear pore complex protein, ALADIN. Clinical features are highly variable, even within families with the same mutation.

Congenital adrenal hypoplasia (also known as *adrenal hypoplasia congenita*) most often occurs as an X-linked disorder caused by mutation in the nuclear receptor DAX1 (NR0B1),[32] which is expressed in the adrenal cortex, gonads, and gonadotrophs, and the ventromedial nucleus of the hypothalamus.[33] Boys with this condition tend to present with salt-losing PAI in infancy (60%) or childhood (40%), followed by hypogonadotrophic hypogonadism secondary to abnormal development of both the hypothalamus and the pituitary. In addition, these boys show disordered tubular structures and Leydig cell hyperplasia. Recent evidence points to the existence of a milder form, with onset in adult life presenting with mild AI and partial hypogonadotropic hypogonadism. The genetic basis for the recessive form of congenital adrenal hypoplasia remains unknown, but homozygous and heterozygous mutations have been described in the *SF-1* gene that produce primary adrenal failure and a female phenotype complete with uterus in an XY male.

Secondary Adrenal Insufficiency. SAI implies a pituitary etiology; in common use it often incorporates hypothalamic (formally tertiary) etiologies. Adrenal insufficiency may develop after prolonged use of exogenous glucocorticoids, reflecting incomplete escape from negative feedback suppression of the HPA axis. This may be termed secondary/tertiary AI, but its unique characteristics (potential reversibility over time with glucocorticoid weaning and its often incomplete extent) suggest it may be considered separately using terms such as adrenal suppression or exogenous AI. The causes of SAI are listed in Table 93.3. The most common cause is HPA axis suppression of CRH and ACTH secretion from prolonged (at least 2–4 weeks) exogenous glucocorticoid administration with a dose exceeding endogenous cortisol production, equating to standard adult replacement doses such as hydrocortisone 15 to 25 mg daily, prednisolone 3 to 5 mg daily, or dexamethasone 0.3 to 0.5 mg daily. Approximately 3% of adults are using glucocorticoids for indications other than adrenal hormone replacement. Adrenal suppression has characteristics that differ from other etiologies of SAI. These include potential reversibility with weaning of exogenous glucocorticoid, high degree of interindividual variability in suppression extent and duration, and a lack of other hypothalamic and pituitary deficits. The likelihood of adrenal suppression, its extent, and time to recovery depend on exogenous glucocorticoid dose, duration, and administration schedule. High-dose glucocorticoid administration for prolonged periods may lead to adrenal suppression lasting 12 to 18 months. Adrenal suppression is most often iatrogenic but may also develop after treatment of endogenous hypercortisolism, following successful surgical or medical treatment of endogenous Cushing syndrome of pituitary, adrenal, or ectopic ACTH tumoral origin (see Chapter 7, 97). Rarely, topical steroid cream can cause adrenal suppression, as can high-dose progesterone such as megestrol therapy. SAI is a risk for patients with inhaled high-dose potent inhaled glucocorticoids

TABLE 93.3 **Causes of Secondary Adrenal Insufficiency**

1. Hypothalamic-pituitary-adrenal suppression
    - A. Exogenous
        - i. Glucocorticoids
        - ii. Opioids
    - B. Endogenous: Cushing syndrome, ACTH-dependent, or ACTH-independent
2. Lesions of the hypothalamus or pituitary gland
    - A. Neoplasm
        - i. Pituitary tumor
        - ii. Metastatic tumor
        - iii. Craniopharyngioma
        - iv. Meningioma
    - B. Craniopharyngioma
    - C. Immune hypophysitis
    - D. Infection
        - i. Tuberculosis
        - ii. Actinomycosis
        - iii. *Nocardia*
    - E. Immune checkpoint inhibitors
3. Sarcoid
4. Head trauma
5. Isolated deficiency of ACTH

ACTH, Adrenocorticotropic hormone.

used in the treatment of asthma.[34] The use of perioperative stress-dose glucocorticoids was instituted after early reports of adrenal crises in relation to surgery; however, traditional doses may be excessive, and newer regimens are likely to produce fewer side effects.[35] Overall, hospitalization with AI or adrenal crisis in patients using exogenous glucocorticoids is rare.[36]

Opioid-Induced Hypothalamic-Pituitary-Adrenal Axis Suppression. Widespread use of opioids for chronic noncancer pain has led to reports of hypoandrogenism, more frequently in men. Suppression of the HPA axis may follow opioid receptor stimulation affecting hypothalamic CRH production and/or superadded peripheral mechanisms; naloxone leads to prompt sequential ACTH and cortisol release when used in high doses, suggesting that relatively low-affinity opioid receptors are involved.[37] Low cortisol and sex steroids potentially add to the disability associated with long-term opioid use. Adrenal insufficiency appears to be related to the cumulative opioid exposure (dose times and duration) and may be diagnosed in 9% to 15% of patients taking chronic opioids.[13] Adrenal crisis has been reported in opioid-induced AI.[38] Recovery of adrenal function may occur following the cessation of opioids.

Other Causes of Secondary Adrenal Insufficiency. Apart from adrenal suppression, other causes of SAI require investigation with a dedicated pituitary magnetic resonance imaging (MRI), with gadolinium unless contraindicated. CT scans and head MRI generally provide less anatomical definition, although CT is sometimes used to reliably delineate calcification. The majority of cases of SAI are structural, such as tumors and granulomatous disease, the result of surgery or radiotherapy in the region, or hypophysitis resulting mostly from autoimmune or immune stimulatory therapies for cancer (see Table 93.3). However, there are many causes, and the imaging characteristics and clinical context are crucial in differential diagnosis. Occasionally, biopsy is required for pathological diagnosis, but often, the risks of biopsy exceed the benefits, and observation with serial imaging is preferred.

The most common tumor etiology of SAI is pituitary adenomas, which can damage pituicytes, generally when in the macroadenoma size range (>10mm), or following pituitary surgery or radiotherapy aimed at controlling pituitary adenomas. Pituitary adenomas may become evident although hypersecretory phenomena resulting from excess prolactin, growth hormone, or ACTH and rarely, thyroid-stimulating hormone (TSH). Hypersecretion of gonadotropins or their fragments is usually asymptomatic. Pituitary tumors of all types often present with structural complications from impingement of adjacent structures such as the optic chiasm/nerves (visual field defects classically bitemporal hemianopia) and extraocular nerves within the cavernous sinus (diplopia). Pituitary tumors may present with SAI and loss of other pituitary hormones. Such losses are often time-sequenced (in order: growth hormone, gonadotropins, TSH, ACTH), so that SAI tends to develop late in the process of compressive hypopituitarism.

Other tumors in the sella turcica and parasellar region may lead to SAI. These include metastases that may progress rapidly, unlike the usual slow-growing pituitary adenomas. Rathke's cleft/pouch cysts may occasionally cause ACTH deficiency and may be complicated with proteinaceous material or hemorrhage so they may be indistinguishable from adenomas on MRI. Craniopharyngiomas arise from craniopharyngeal duct epithelium and may be located in the sella turcica, in the suprasellar region, or in the third ventricle floor. They are divided into adamantinomatous and papillary histological types arising from tumor mutations of the *β-catenin* and BRAFV600E genes, respectively.[39] Treatment with surgery and radiotherapy may lead to both pituitary (hormone deficits) and hypothalamic (appetite, weight, temperature, neurocognitive deficits) injury.

Nontumor pathologies in the pituitary can lead to SAI. These include inflammation of lymphocytic type, considered likely to be autoimmune, which may present with an acute inflammatory mass, especially in relation to pregnancy or following IgG4-related disease.[40] Silent autoimmunity may produce hypopituitarism, including isolated ACTH deficiency, and hence SAI. Infections in the region include bacterial pituitary abscess or chronic infections such as actinomycosis and nocardiosis. Granulomatous disorders affecting the pituitary include sarcoid, amyloid, and Langerhan's cell histiocytosis, all of which represent systemic disorders that may produce disease outside the pituitary or may be isolated to the pituitary. Haemochromatosis can result in ACTH deficiency, believed to be secondary to hypothalamic injury. Sheehan syndrome, or hypopituitarism after childbirth, generally follows a postpartum hemorrhage with shock and hypoperfusion to an enlarged hypervascular pituitary with consequent infarction, classically presenting with loss of lactation. Head trauma may also lead to SAI and other pituitary hormone deficits.[41]

Checkpoint inhibitor therapy, used for melanoma and other malignancies, includes the CTLA-4 inhibitor ipilimumab, which has a dose-related risk of hypophysitis, generally isolated ACTH deficiency that is not reversible, in up to 20% of treated cases and may rarely produce PAI (1% risk); PD-1 antibodies and PD-L1 antibodies incur lower rates of AI.[12]

Inherited forms of isolated ACTH deficiency present in childhood.[42] Some of these patients demonstrate mutations in the *T-Pit* (*TBX-19*) gene, which encodes an essential transcription factor for *POMC* gene expression in corticotroph cells. Other genetic forms of SAI include mutations of key pituitary transcription factors, *PROP1*, *PIT-1,* and the *POMC* gene itself. SAI may also follow gene defects involving hypothalamic function such as those of the *CRH* gene or the gene encoding the CRH receptor. Several developmental disorders of the brain may be associated with hypopituitarism, likely from hypothalamic dysfunction, including septooptic dysplasia and optic nerve dysplasia.

CRITICAL ILLNESS-RELATED CORTICOSTEROID INSUFFICIENCY

Patients with critical illness are subject to profound physiological stress, with multiple stimuli such as fever, elevation of inflammatory cytokines, pain, and hypovolemia leading to activation of the HPA axis. Cortisol has a pivotal role in maintenance of homeostasis and in immunomodulation in critical illness. Routine measurements of serum cortisol may not reflect end-organ glucocorticoid sufficiency because of tissue resistance to cortisol and reduced concentrations of the principal carrier proteins for cortisol, corticosteroid-binding globulin (CBG) and albumin. Free cortisol correlates more closely with illness severity. Septic shock, a common state and important cause of mortality, which has a 30% to 40% mortality rate despite standard antibiotics, fluids, and catecholaminergic vasopressors, has been studied extensively over the past two decades from the point of view of glucocorticoid therapy. Earlier studies of high-dose short-term synthetic glucocorticoids for septic shock showed increased mortality. Continuing clinical observations of benefit from hydrocortisone in septic shock led to a succession of small trials revealing salutary effects such as a pressor response[43] and reduced inflammatory cytokines,[44] ultimately leading to progressively larger multicenter randomized controlled trials of "low-dose" hydrocortisone. The general conclusion is that randomly administered hydrocortisone, generally 200 mg daily, leads to reduced time-to-withdrawal of vasopressor support (1–2 days) and a possible small benefit in mortality.[45-47] Sicker patients and, curiously, those treated with fludrocortisone may benefit more in terms of mortality. It may be that a subset of patients benefit more from hydrocortisone. A state of reduced cortisol response to cosyntropin (ACTH 1–24) 250 μg (<9 μg/dL [<248 nmol/L] at 60 mins) may identify a state of relative AI, later referred to as CIRCI, although routine ACTH stimulation testing is not supported on a consensus basis.[15] Mechanistically, CIRCI has been considered to potentially result from adrenal damage, inhibition of steroidogenesis, reduced hypothalamic-pituitary drive, reduced cortisol transport and delivery—inhibition of CBG synthesis, reduced albumin, CBG cleavage-mediated exhaustion of CBG, reduced cortisol metabolism (5α reductase in the liver, 11β-hydroxysteroid dehydrogenase in the kidney), and glucocorticoid resistance—and excessive NF-κB activation inhibits GR-α activity.[48] Initial studies suggested that CIRCI predicted mortality benefit from parenteral hydrocortisone, but this was not confirmed in larger trials. Early studies in septic shock with higher rates of CIRCI appear to have been affected by the use of etomidate[49] or compromised by insufficient statistical power. The two largest trials in septic shock have shown benefits in required duration of vasopressor treatment, but only the study with the higher mortality rate showed a mortality benefit.[45,47]

At present, hydrocortisone 200 mg daily, 50 mg four times daily, or by intravenous infusion for 7 days without taper, perhaps with fludrocortisone 0.05 mg enterally via nasogastric tube daily, is considered indicated in patients with hypotension despite fluid resuscitation and vasopressor treatment.[15] The effects of cortisol concentrations achieved by these doses (~3000 nmol/L, 109 μg/dL) include attenuation of the inflammatory cytokines IL-6 and IL-8; soluble E-selectin, a factor important in endothelial-granulocyte interactions; expression of the neutrophil activation markers CD11b and CD64; and the antiinflammatory cytokines IL-10 and soluble TNF receptors I and II. Markers of monocyte function such as HLA-DR antigen expression and *in vitro* phagocytosis are not affected, nor are the Th1 function markers IL-12 and IFN-γ.[50] Overall, these hydrocortisone responses are considered antiinflammatory rather than immunosuppressive.[50] Other critical illnesses where hydrocortisone therapy may be clinically indicated include hospitalized community-acquired pneumonia, acute respiratory distress syndrome, and bacterial meningitis.[48] A place for hydrocortisone in severe trauma is not established.

DIAGNOSIS OF ADRENAL INSUFFICIENCY

In times of clinical urgency, serum cortisol is the most important test in diagnosing AI. Very low or clearly normal concentrations are useful, but circadian and ultradian pulsatile cortisol secretion make random cortisol testing unreliable. A morning plasma cortisol below 3 μg/dL (83 nmol/L) is indicative of AI, whereas cortisol above 19 μg/dL (525 nmol/L) rules out the disorder. Morning serum cortisol concentrations within 1 hour of waking are generally high; hence, low cortisol values at this time are suspicious for AI. The specificity of morning cortisol concentrations in ruling out AI, obviating the need for ACTH stimulation testing, depends on the cortisol level chosen—for example, in one study a cortisol, a cutoff of greater than 236 nmol/L (8.6 nmol/L) was 71% specific for ruling out AI, and a cutoff of 375 nmol/L (13.6 μg/dL) was 95% specific.[51] Basal cortisol should be taken as soon as possible after waking because serum cortisol concentrations fall by 30 nmol/L (1.2 μg/dL) per hour between 7:00 AM and 12:00 PM.[52] In clinical practice the extent to which AI needs to be ruled out will take into account clinical factors that increase or decrease the degree of clinical suspicion. For example, the presence of hypertension makes AI very unlikely. In patients with typical clinical features of AI, the presence of a very low serum cortisol is likely to be diagnostic and should be met with a rapid, often within hours, recovery of well-being and function that is itself confirmatory. Similarly, values less than 7 μg/dL (200 nmol/L) in severely unwell individuals with features of AI are suspicious for AI. In the appropriate context, given a clear clinical picture, it is inappropriate to delay glucocorticoid treatment to allow the more definitive testing. Cosyntropin, if required, can be administered after appropriate resuscitation. Common HPA axis pharmacologic stimuli include cosyntropin, insulin hypoglycemia, or metyrapone.[53] The cortisol responses to these tests have generally been compared among tests in patients and healthy controls, rather than related to the clinical effects of glucocorticoid administration.

Adrenocorticotropic Hormone Stimulation Testing

Stimulation of the adrenals with synthetic ACTH, comprising N-terminal amino acids 1–24 of the complete 39-amino acid peptide, in a dose of 250 μg delivered intravenously (IV) or intramuscularly (IM) at any time of day, with a serum cortisol at baseline and at 30, and/or 60 minutes, has long been the standard of care test for cortisol deficiency. The test depends on the fact that the normal adrenal gland, under maximal and acute ACTH stimulation, produces a peak plasma cortisol concentration of approximately 18 μg/dL (500 nmol/L) (assay-dependent) at the lower boundary of the normal range. Cortisol assays vary widely, and it is important to refer to ranges supplied by assay manufacturers.[54] Compared with liquid chromatography tandem mass spectroscopy (LCMS-MS), immunoassays generally overestimate cortisol concentration. Cosyntropin stimulation is rapid, insensitive to interference from diet or medication, simple to interpret, and reliable, and it can be applied to people of all ages without fear of untoward effects, although anaphylaxis has been reported rarely. Similar times and criteria have been demonstrated after IM administration.

A normal cortisol response to cosyntropin renders AI extremely unlikely. However, some factors need to be considered. First, this is a test of *adrenal* function; therefore, if it is used as an assessment of *pituitary*-adrenal function, the indirect nature of the test must be appreciated. For example, although hypothalamic-pituitary failure eventually will lead to adrenal hypofunction, and a close agreement between tests of HPA function has been demonstrated, there are exceptions. In particular, a patient who has been recently rendered hypopituitary after pituitary surgery may show a maintained response to cosyntropin stimulation for 4 to 6 weeks while being profoundly ACTH and cortisol deficient.[55] In addition, patients using oral estrogen have higher total cortisol levels because of increased synthesis of CBG and can be misinterpreted as normal despite having AI. Finally, some patients with chronic fatigue syndrome or fibromyalgia may show marginally low cortisol responses to ACTH but use of glucocorticoid therapy is not recommended.

The 250-μg cosyntropin dose is the only dose commercially available. Cosyntropin represents ACTH 1–24, the bioactive N-terminal fragment of full-length ACTH (a 39-amino acid peptide). There is considerable clinical experience with its use, although ACTH concentrations after injection are clearly supraphysiologic. Some studies have suggested possible increased sensitivity of ACTH stimulation testing in patients with SAI when a low dose of 1 μg of ACTH is employed, this dose being closer to the peak of the dose-response curve for synthetic ACTH. However, a systematic review and metaanalysis of ACTH stimulation studies for diagnosis of SAI (n = 30 studies) and PAI (n = 5 studies) showed similar diagnostic accuracy of the two ACTH doses (1 μg and 250 μg).[56] The dilution of the prepared 1 μg/mL solution of ACTH used clinically may vary substantially, which introduces uncertainty to the test result.

Plasma ACTH separates patients with PAI from those with SAI. In primary disease, plasma ACTH usually is greatly increased, with values greater than 100 pg/mL (22.0 pmol/L).[21]

Overnight Metyrapone Test

Metyrapone is administered at midnight, as a single dose test at 30 mg/kg body weight. Measurements of the 11-deoxycortisol and cortisol are obtained the following morning. Metyrapone blocks the conversion of 11-deoxycortisol to cortisol by 11β-hydroxylase, inducing a rapid decrease of cortisol and an increase in its precursor 11-deoxycortisol because of the increased ACTH secretion. A failure of 11-deoxycortisol levels to rise following the overnight administration of metyrapone indicates either ACTH deficiency or primary adrenal disease. The overnight metyrapone test is mainly used to diagnose partial defects in ACTH secretion. A decline in 8:00 AM. serum cortisol to less than 7 μg/dL (172 nmol/L) confirms compliance with metyrapone administration, and an 8:00 AM serum 11-deoxycortisol of less than 7 to 10 μg/dL, or less than 7 μg/dL (202 nmol/L), is diagnostic of AI.[57]

Insulin Tolerance Test

Insulin-induced hypoglycemia is a well-known test of cortisol reserve.[58] This stimulus depends on intact hypothalamic stimulation of pituitary ACTH secretion and on the ability of the adrenal gland to respond to ACTH with the secretion of cortisol. Thus, a normal test indicates a functioning HPA axis. An abnormal test implies a lesion in this system that can be anywhere between the hypothalamus and the adrenal gland. The usual test is performed by administering 0.15 unit/kg of regular insulin IV as a bolus and measuring blood glucose and cortisol at 15-minute intervals throughout the subsequent 2 hours. The blood glucose level must fall below 45 mg/mL (<2.2 mmol/L) to ensure adequate stimulation for interpretation of the test. The normal response is a plasma cortisol of greater than 20 μg/dL (550 nmol/L, assay dependent) at any time during the test. The test requires close observation to avoid severe prolonged hypoglycemia but can be done safely in selected patients at low risk of coronary ischemia or seizures.

Adrenal Autoantibody Tests

As mentioned above, antibodies against the adrenal biosynthetic enzyme 21-hydroxylase are present in more than 90% of patients with recent-onset autoimmune adrenalitis and are recommended in all cases of PAI, unless the cause is obvious. Antibodies against the adrenal side-chain cleavage enzyme are present less frequently and associated with premature ovarian failure.

Serum 17-Hydroxyprogesterone

Serum 17-hydroxyprogesterone is the cornerstone of diagnosis of 21-hydroxylase deficiency. In many regions, it is measured in newborns to reduce risk of adrenal crises in the first week of life, particularly in boys, where genital ambiguity is not present at birth. This testing is followed by ACTH stimulation testing for confirmatory purposes. Further clarification may be obtained through *CYP21A2* gene sequencing, a measure that may be useful in genetic counseling. Serum 17-hydroxyprogesterone concentration diagnostic cutoffs are assay-specific.

Very Long Chain Fatty Acids

Males with isolated AI, without evidence of autoimmunity, should be tested for VLCFAs to exclude X-linked ALD or AMN. Up to 20% of males with elevated VLCFA levels may have PAI, and neurological features may not be evident for up to 2 years.[59]

Adrenal Imaging

Imaging is not essential for diagnosis of autoimmune AI, and an atrophic gland may be difficult to visualize. In patients with negative 21-hydroxylase antibodies or where clinical suspicion of a nonautoimmune etiology such as hemorrhage, infection, infiltration, or neoplastic disease exists, abdominal CT should be performed.

KEY POINTS

- Cortisol deficiency is the hallmark of adrenal insufficiency.
- Adrenocorticotropic hormone (ACTH) stimulation testing is the primary diagnostic test for cortisol deficiency and is more reliable than random serum cortisol.
- Elevated serum ACTH concentration establishes primary adrenal insufficiency and excludes pituitary/hypothalamic etiology.
- Measurement of serum aldosterone and renin concentrations determines if adrenal aldosterone secretion is intact.
- 21-hydroxylase antibodies are a useful adjunct to determine an autoimmune etiology in primary adrenal insufficiency. Elevated serum 17-hydroxyprogesterone concentrations are a key diagnostic feature of 21-hydroxylase deficiency.
- Imaging of the adrenals is needed in cases of primary adrenal insufficiency where a nonautoimmune etiology is considered likely, and imaging of the pituitary/hypothalamus is generally required in secondary adrenal insufficiency.

TREATMENT OF ADRENAL INSUFFICIENCY

Treatment for AI consists of replacement of the missing steroid hormones: cortisol in SAI and cortisol and aldosterone in PAI. The glucocorticoids employed include naturally occurring hydrocortisone (cortisol) and cortisone acetate and the synthetic steroids prednisolone and the less frequently used dexamethasone, although the latter is not recommended, as patients are easily overtreated, leading to Cushingoid side effects. These glucocorticoids differ in potency, with equivalent replacement daily doses and serum disappearance half-lives ranging from 15 to 25 mg and 90 min for hydrocortisone, 20 to 30 mg and 90 min for cortisone acetate, 3 to 5 mg and 120 min for prednisolone, and 0.3 to 0.5 mg and 190 min for dexamethasone. All have mineralocorticoid activity except dexamethasone. For example, hydrocortisone has 1/400th the mineralocorticoid potency of fludrocortisone by virtue of the 9α fluorine atom that confers resistance to metabolism by 11β-hydroxylase type 2, so that 40 mg hydrocortisone has the mineralocorticoid activity of 0.1 mg fludrocortisone.

Hydrocortisone is currently the main glucocorticoid recommended in AI. In previous decades relatively high doses of hydrocortisone and other glucocorticoids were used, based on erroneous estimates of cortisol production rates. Subsequent studies estimated lower daily cortisol production rates in adults and children at approximately 5.7 to 6.8 mg/m^2/day, or approximately 10 mg per day, equating to oral hydrocortisone dosing of 15 to 25 mg/day, or prednisolone 3 to 5 mg/day because of estimated pharmacokinetics and metabolism.[21]

Retrospective studies showed lower bone mineral density, greater body weight, and higher blood pressure in glucocorticoid-treated patients,[60] with a negative effect of glucocorticoid dose, although factors other than dose may have contributed. A limitation of retrospective studies in this area is that the indication(s) for use of higher hydrocortisone equivalent doses, generally above 30 mg daily, is unclear.

Many dosing schedules for hydrocortisone have been used. A double-blind crossover study of two-dose versus four-dose daily hydrocortisone showed a more physiological serum diurnal cortisol pattern with four doses per day and a patient preference for that regimen.[61] Systematic analyses designed to obviate such biases have not shown any effect of glucocorticoid dosing schedule on well-being and found that bone density data are inconsistent. Dose regimens vary depending on the relative priorities of pursuing diurnal cortisol patterns—requiring more frequent dosing in an effort to improve well-being, or less frequent dosing to improve medication adherence and convenience. One common regimen may be hydrocortisone 10 mg on rising, 5 mg at lunchtime, and 5 mg in the early evening. The final dose regimen is then modulated according to clinical response and patient preference. Observation for side effects includes growth velocity monitoring in children and measurements of weight and waist circumference and examination for features of incipient Cushing syndrome in adults, as well as resolution of clinical features of AI. No objective measures are available to assist in glucocorticoid dose adjustment—the use of ACTH is unreliable, as the disturbance in cortisol/ACTH feedback in PAI leads to elevated ACTH in apparently well-treated PAI patients, and ACTH is absent or unrelated to glucocorticoid dose in SAI. Pregnancy is associated with elevated cortisol secretion and increases in total and free cortisol in serum, reaching approximately 2.5-fold normal in late third trimester, driven by placental CRH.[62] No studies guide glucocorticoid dose adjustment, but an increased dose of 20% to 40% is suggested after 24 weeks.[21] Use of dexamethasone is not recommended, as it is not metabolized in the placenta, so fetal glucocorticoid exposure may be excessive.

Hydrocortisone metabolism is highly variable, such that individuals taking 0.2 to 0.3 mg/kg/day have cortisol levels that substantially overlap those of patients taking 0.4 to 0.6 mg/kg/day.[63] In associated analyses, the higher hydrocortisone dose was associated with better quality of life,[64] higher blood pressure (BP) (by 5/2 mm Hg), and no negative effects on cognition.[65] Other studies in PAI and CAH have suggested that lower doses of short-acting glucocorticoids may be associated with an increased risk of adrenal crises.[66,67] The use of prednisolone with its longer serum half-life compared with hydrocortisone (150 vs. 90 minutes) may make once-daily dosing more feasible if required.

Plenadren contains immediate- and delayed-release (dual-release) hydrocortisone given on awakening. Cortisol levels are quite physiological, but there is no early morning prewakening cortisol rise as seen in normal physiology. A 12-week open trial showed weight reduction and improved glucose tolerance, blood pressure, and quality of life. A further single-blind study that took place over 24 weeks showed a lower weight difference (4 kg) between the groups receiving Plenadren and rapid-release hydrocortisone, with 1.9-kg gain in the rapid-release group. However, glucocorticoid exposure may have been lower in the Plenadren group despite the same dose, because of altered pharmacokinetics.[68] Chronocort is a twice-daily hydrocortisone tablet designed to be taken in the morning and at bedtime where favorable circadian cortisol concentrations are apparent—there may be advantages in control of androgens in CAH, but these have not been demonstrated in a larger multicenter trial.[69] Longer-acting glucocorticoids (plasma half-life 150 mins prednisolone vs. 90 mins for hydrocortisone) are more convenient than hydrocortisone, but at present there are no reported studies of the relative benefits of prednisolone. The provision of circadian cortisol concentrations in a double-blind study of subcutaneously infused hydrocortisone showed no effect on well-being,[70] although a positive effect was seen in an open crossover study.[71] To date, no double-blind study of delayed or dual-release tablets has been performed to address the well-being question definitively.

The only preparation available to specifically replace aldosterone is fludrocortisone, at a once-daily maintenance oral dose of 50 to 300 μg/day. A typical starting dose in adults and children is 100 μg daily. Response is monitored in terms of serum sodium, potassium, and renin levels, taken in the seated position with reference to blood pressure. Peripheral edema is a common problem on instituting fludrocortisone in new patients with PAI and may make low doses necessary for a period of time. No parenteral preparation of fludrocortisone is available.

KEY POINTS

- Adrenal hormone replacement consists of glucocorticoid tablets, taken at a dose and frequency of administration consistent with physiological cortisol secretion, with reference to the potency and elimination half-life/tissue effect of the steroid employed.
- Typically, hydrocortisone doses are 15 to 25 mg per day, or prednisolone 4 to 6 mg per day, but some patients do require higher doses, as glucocorticoid metabolism and tissue sensitivity display considerable interindividual variability. Dose adjustment requires careful clinical assessment and judgment, as no pathology tests are helpful.
- Mineralocorticoid replacement is often needed in primary adrenal insufficiency and involves fludrocortisone, typically 0.1 to 0.3 mg. Dose adjustment primarily involves control of symptoms of aldosterone deficiency and normalization of serum potassium and renin.

Replacement of Dehydroepiandrosterone

Given that dehydroepiandrosterone (DHEA) and its sulfated entity DHEA-S are the most abundant steroids secreted by the adrenal, attention has focused on the value of replacement of DHEA, which is generally present in very low concentrations in AI patients relative to healthy individuals. The role of DHEA in pregnancy, where secretion by the fetal adrenal, providing substrate for placental estriol production, is well-established, as is as its role in producing axillary and pubic hair in adolescents, a phenomenon known as adrenarche. It cannot be said that DHEA has other roles mandating replacement in adults, although it assists in maintaining terminal hair in the pubic and axillary areas, where the skin has high androgen sensitivity, in women. In AI, DHEA has been employed to help combat the known reduced quality of life compared with normal individuals despite adequate glucocorticoid and mineralocorticoid replacement. Several short-term trials in PAI and SAI have shown that DHEA replacement potentially improves mood and well-being, but beneficial effects have not been reported by all. A metaanalysis of these trials in women with PAI or SAI showed small (perhaps trivial) effects on quality of life and depression, but no effect on anxiety or sexual well-being, with the evidence appearing insufficient to support routine use of DHEA.[72] There are no data regarding the long-term safety of DHEA administration in AI. DHEA can be trialed for patients whose well-being is severely impaired despite optimal glucocorticoid and mineralocorticoid replacement. A daily dose of 10 to 25 mg DHEA taken in the morning with monitoring of therapy with serum DHEA to target the middle of the normal range can be trialed.

KEY POINTS

- Although circulating dehydroepiandrosterone (DHEA[-S]) concentrations are often low in adrenal insufficiency, replacement of DHEA is not routinely required, as consistent benefits have not been demonstrated in short-term trials.
- DHEA treatment may be considered in selected patients and should be delivered as a trial, monitoring clinical benefits and side effects (if any) while aiming for normal serum DHEA-S concentrations.

Quality of Life in Adrenal Insufficiency

A substantial minority of patients with PAI complain of persistent poor quality of life with reduced work capacity and increased use of social welfare, as systematically verified in Scandinavian studies.[60] It is not known why patients with AI have reduced quality of life despite appropriate adrenal hormone replacement, and it is likely that individual factors are important. Possibilities include periods of inadequate hydrocortisone exposure, low glucose concentrations at time of cortisol deficiency, lack of DHEA, and synergy from associated hormone deficits in autoimmune polyglandular syndromes. Patients often find glucocorticoid replacement regimens a burden, to an extent that seems to correlate with their illness severity perception.[20]

Adrenal Suppression

Management of adrenal suppression involves a graded withdrawal of exogenous glucocorticoid so that the endogenous HPA axis function can recover, a process that may take 6 to 18 months. Adrenal suppression is often partial. Patients taking 5 to 10 mg prednisolone daily comprise approximately one-third with unsuppressed cortisol response to ACTH 1–24, one-third with complete suppression of cortisol response to ACTH, and one-third partially suppressed.

Weaning of glucocorticoids requires three considerations:

1. The possibility of recrudescence of the underlying disorder, most often inflammatory, that prompted use of chronic supraphysiologic glucocorticoids.
2. The appearance of glucocorticoid withdrawal syndrome, a symptom complex that also occurs with withdrawal of other hormones. Symptoms often overlap with those of AI, despite a glucocorticoid dose exceeding the physiological range.
3. True AI developing when the glucocorticoid (GC) dose is below the physiological replacement range.

In general, as long as there is no disease recrudescence, glucocorticoid doses can be weaned quite quickly above the physiological range, but need to be withdrawn at a much slower pace when withdrawing within the physiological range. For example, with prednisolone, doses can be reduced by as much as 20% per week above 5 mg daily. The rate of glucocorticoid dose reduction needs to be individualized, with AI symptoms and morning serum cortisol, before morning prednisolone dosing, acting as arbiters of the rate of prednisolone withdrawal. In general, morning cortisol levels above 400 nmol/L suggest that rapid withdrawal or cessation of prednisolone is indicated; cortisol below 200 nmol/L suggests that withdrawal may need to be stopped until cortisol levels rise; and levels of 200 to 400 nmol/L suggest that slow withdrawal may be continued as long as the patient is asymptomatic. Recovery can also be gauged by the response of plasma cortisol to an IV injection of cosyntropin, with recovery being indicated by a plasma cortisol level greater than 18 μg/dL (500 nmol/L) at intervals based on clinical judgment when there is a need to verify adrenal secretory status. Stress dosing of glucocorticoids may be necessary for up to 1 year after glucocorticoid withdrawal to avoid adrenal crisis.

KEY POINTS

- Quality-of-life impairments are common in treated adrenal insufficiency; there are many possible causes. Optimization of adrenal hormone replacement and consideration of extraadrenal causes are necessary first steps in management. Despite standard assiduous management, there remain a proportion of patients with poor quality of life—an area where systematic study is needed to help provide new therapeutic approaches.
- Adrenal suppression resulting from the therapeutic use of supraphysiologic glucocorticoid doses for inflammatory and other disorders is unique in its reversibility, requiring gradual stepwise withdrawal of glucocorticoid replacement while observing progress of the underlying disease, Cushingoid features, and the presence of relative or absolute adrenal insufficiency. Morning cortisol and/or adrenocorticotropic hormone stimulation may help guide the rapidity of glucocorticoid withdrawal.

ADRENAL CRISIS

Adrenal crises may be defined as an acute deterioration in health status associated with hypotension—absolute hypotension (systolic blood pressure <100 mm Hg in an adult) or relative (systolic blood pressure at least 20 mm Hg lower than usual)—with features that resolve within 1 to 2 hours of parenteral glucocorticoid administration (i.e., a marked resolution of hypotension within an hour and improvement of clinical symptoms over 2 hours).[20] Approximately 6% to 8% of patients with AI will have an single incident of adrenal crisis per year, and rates appear to be rising with lower-dose, short-acting glucocorticoid regimens.[20] Adrenal crises are more common in patients with PAI than in those with SAI, probably owing to partial preservation of cortisol secretion in some patients with SAI and the absence of mineralocorticoid secretion in PAI. Some AI patients experience multiple episodes, while others have few or no episodes.[73] Susceptibility to adrenal crises varies among patients with hypoadrenalism, depending on a number of factors, including age, prior adrenal crises, the presence of APS-I, diabetes mellitus, and nonendocrine comorbidities, such as asthma and cardiac disease, which increase risk.[74] Adrenal crisis mortality may be as high as 6% per event.[73] Adrenal crisis has been reported in patients without an established diagnosis of AI, although typical symptoms may have been present in retrospect.[67]

Treatment of Adrenal Crisis

Treatment includes administration of intravenous hydrocortisone, 100 mg IV, followed by 200 mg/24 hours as a continuous infusion or as IV (or IM) hydrocortisone 50 mg every 6 hours, with subsequent does tailored to clinical response. Hydrocortisone can be substituted with methylprednisolone 40 mg/24 hours or dexamethasone 4 mg every 24 hours if necessary—use of dexamethasone would make it necessary to give fludrocortisone, which is unnecessary for high doses of hydrocortisone or

Fig. 93.4 A–E, Strategies used to prevent adrenal crises. Initially, use of stress dosing in illness is crucial. For patients unable to take glucocorticoid tablets, injections of hydrocortisone, most conveniently stored and delivered using the Solucortef Actovial device are very useful. For patients unable to communicate, the use of medical jewelry such as MedicAlert and carrying a card with details regarding the imperative for parenteral hydrocortisone may also be life saving.

prednisolone, as these steroids have substantial mineralocorticoid activity. Replacement of fluid with normal saline is needed, according to standard resuscitation guidelines; typically volumes of 2 to 3 liters are required, but this may be higher in cases with fluid loss related to the adrenal crisis precipitant, such as gastroenteritis. Rapid clinical improvement is expected, often within 1 hour; if such an improvement is not seen, especially with respect to blood pressure, another cause of shock should be sought.[21]

Prevention of Adrenal Crises

The effectiveness of preventive measures, largely patient-initiated, is incomplete, with intensive education not apparently affecting adrenal crisis risk in one prospective study.[73] Patients with PAI, chronic symptoms suggestive of AI perhaps reflecting underreplacement, poor well-being, or previous episodes of adrenal crises are more likely to develop adrenal crises.[75] The three standard measures are:

1. “Stress dosing” with intercurrent illness, especially infections with fever, where the replacement dose is increased 3-fold for 3 days (“3 × 3 rule”) or until the illness subsides.
2. Use of injectable hydrocortisone (Solucortef Actovial 100 mg) (Fig. 93.4), which can be delivered IM (or subcutaneously if needed)[76] in unwell patients by the patient or relatives when unable to take or reliably absorb tablets, for example in gastroenteritis.
3. The provision of a communicative device to inform emergency medical staff of the need for parenteral hydrocortisone when the patients is unable to effectively communicate this. Such devices include MedicAlert jewelry and/or emergency measures in the form of a “steroid card” carried by the patient. A European Emergency card has been introduced that is translated into numerous languages (see Fig. 93.4).

Studies have shown that subcutaneous hydrocortisone is well-absorbed.[77] Although studies of subcutaneous hydrocortisone in adrenal crisis (AC) prevention in actual or incipient crisis have not been performed; such administration is surely superior to no parenteral dosing at all, recognizing that many patients have difficulty with self-administration of IM injections.

Crucial in adrenal crisis prevention is the management of perioperative patients. In general, AI patients all require ongoing glucocorticoids with surgery, and, as surgical stress is associated with a physiological rise in cortisol, it is customary to recommend parenteral (or sometimes oral) glucocorticoids in a dose commensurate with the extent of the surgery. Many schema have been produced and are approved on a consensus basis, and examples are freely available, such as: www.addisons.org.uk/surgery (Table 93.4).

KEY POINTS

- Adrenal crises are life-threatening medical emergencies.
- Prevention is possible using a combination of patient education, patient-driven stress dosing of glucocorticoid, home parenteral hydrocortisone, and use of MedicAlert jewelry/patient information cards to advise clinicians to promptly administer hydrocortisone in patients unable to do so themselves.
- Prompt delivery of parenteral hydrocortisone is needed on patient presentation at medical facilities to avert worsening of the clinical features of incipient or actual adrenal crisis.
- Treatment of adrenal crises involves parenteral glucocorticoids and standard fluid resuscitation, as well as addressing any evident medical precipitant.

TABLE 93.4 **Dosing Strategies for the Perioperative Management of Patients With Adrenal Insufficiency**

	Steroid-Dependent Patient Requires Continuous/Parenteral Steroid Cover	**See Surgical Guidelines: www.addisons.org.uk/surgery**
TYPE OF PROCEDURE	***PREOPERATIVE AND OPERATIVE NEEDS (SEE NOTES 1, 2)***	***POSTOPERATIVE NEEDS (SEE NOTES 6, 8, 9)***
Lengthy, major surgery with long recovery time, e.g., open heart surgery, major bowel surgery	100 mg hydrocortisone IM or IV just before anesthesia (see Notes 2, 3, 7), immediately followed by: • 100 mg IM or IV 6 hourly or • continuous infusion 200 mg/24 hours	100 mg IM or IV every 6 hours or continuous IV infusion 200 mg/24 hours (see Notes 3, 5) or until able to eat and drink normally (discharged from ITU). If well, then double oral dose for 48+ hours. Then taper the return to normal dose.
Major surgery with rapid recovery, e.g., caesarean section, joint replacement	100 mg hydrocortisone IM or IV just before anesthesia (see Notes 2, 6, 7), immediately followed by: • 100 mg IM or IV 6 hourly or • continuous infusion 200 mg/24 hours	100 mg IM or IV or continuous infusion 200 mg/24 hours for 24–48 hours (see Notes 3, 5) for 24–48 hours (or until able to eat and drink normally). If well, then double oral dose for 24–48 hours. Then return to normal dose.
Labor and vaginal birth	100 mg hydrocortisone IM or IV at onset of active labor (see Notes 4–7), immediately followed by continuous IV infusion 200 mg/24 hours or 100 mg IM or IV 6 hourly until delivery	Double oral dose for 24–48 hours after delivery. If well, then return to normal dose.
Minor surgery, e.g., cataract surgery, hernia repairs, laparoscopy with local anesthetic	100 mg hydrocortisone IM just before anesthesia (see Note 6)	Double oral dose for 24 hours. Then return to normal dose.
Minor procedure, e.g., skin mole removal with local anesthetic	Take an extra oral dose 60 minutes ahead of the procedure	An extra dose 60 minutes after the procedure. Then return to normal dose.
Invasive bowel procedures requiring laxatives, e.g., colonoscopy, barium enema	Hospital admission overnight with IV fluids and 100 mg hydrocortisone: • IM during preparation (see Notes 3, 5, 6) • 100 mg hydrocortisone IM at commencement (see Notes 1, 6)	Double dose oral medication for 24 hours. Then return to normal dose.
Other invasive procedures, e.g., endoscopy, gastroscopy	100 mg hydrocortisone IM just before commencing	Double-dose oral medication for 24 hours. Then return to normal dose.
Major dental surgery, e.g., dental extraction(s) with local or general anesthetic	100 mg hydrocortisone IM just before anesthesia (see Notes 6, 7, 8)	Double-dose oral medication for 24 hours. Then return to normal dose.
Dental surgery, e.g., root canal work with local anesthetic	Double oral dose (up to 20 mg hydrocortisone) 1 hour before surgery	Double-dose oral medication for 24 hours. Then return to normal dose.
Minor dental procedure, e.g., replace filling, scale and polish	Take an extra oral dose. 60 minutes ahead of the procedure	An extra dose where hypoadrenal symptoms occur afterwards. Then return to normal dose.

NOTES

1. Give the steroid-dependent patient first-on-the list status (alongside insulin-dependent diabetes) to minimize the risks of dehydration.
2. For any nil-by-mouth regimen, arrange an IV saline infusion (0.9% saline or equivalent) to prevent dehydration and maintain mineralcorticoid stability, e.g., 1000 mL every 8 hours if >50 kg.
3. Continuous IV hydrocortisone infusion is preferable to 6 hourly IM or IV injection, as it gives more stable cover. Arrange as 100-mg bolus followed by 8.33 mg per hour or 200 mg per 24 hours.
4. Active labor is cervical dilation >4 cm.
5. Arrange continuous IV infusion cover for steroid-dependent patients taking CYP3A4 accelerants, e.g., anticonvulsants, rifampicin, and antifungal drugs, to minimize the risk of decompensation.
6. IM hydrocortisone is preferable to IV injection for its more sustained duration.
7. Administer bolus hydrocortisone over a minimum of 10 minutes to prevent vascular damage.
8. Hydrocortisone acetate cannot be used because of its slow-release, microcrystalline formulation. Ensure parenteral drug is hydrocortisone sodium phosphate or hydrocortisone sodium succinate, 100 mg.
9. Monitor electrolytes and blood pressure postoperatively for all procedures requiring parenteral steroid cover. If the patient becomes hypotensive, drowsy, or peripherally shut down, administer 100 mg hydrocortisone IV or IM bolus immediately.
10. If any postoperative complications arise, e.g., fever, delay the return to normal dose.
11. Ensure back-up supplies of oral and injectable hydrocortisone are available for resuscitation before commencing surgery. Even at full steroid cover, postoperative resuscitation may occasionally be required.
12. A preassessment meeting with the anesthetist is advisable for all steroid-dependent patients to ensure any comorbidities and potential drug interactions are taken into account.
13. Patients who have been taking 5 mg prednisolone or more long term should be regarded as potentially suppressed and managed with perioperative supplemental steroid cover, on a precautionary basis.

The Need for Novel Treatments for Adrenal Insufficiency

The major problems with current adrenal hormone replacement therapy are the poor well-being in a substantial minority of patients and the ever-present risk of adrenal crisis. At present no test accurately assesses the adequacy of glucocorticoid replacement. A test that assessed tissue glucocorticoid sufficiency would be a significant advance and would allow individualized glucocorticoid dose optimization. Some forms of AI have specific difficulties with current therapy. For example, CAH resulting from 21-hydroxylase deficiency has the dilemma that replacement-level glucocorticoids fail to suppress androgen production, and higher doses may control androgens but have Cushingoid side effects (see Chapter 94).

In principle, CAH patients may achieve restoration of adrenocortical function using gene transfer to obviate enzyme deficiencies, as described in rodent models.[78] For patients with autoimmune-based Addison disease, attempts have been made to determine if remnant adrenocortical cells from the autoimmune process, analogous to surviving β cells in type 1 diabetes, may respond to regenerative approaches. Adrenocococrtical stem cells, which have a subcapsular location, proliferate and differentiate into the adrenal steroid secretory cells under the influence of ACTH.[79]

In one study of 13 PAI patients who received 20 weeks of depot ACTH 1–24, two patients achieved stimulated serum cortisol concentrations of greater than 400nmol/L: one was independent of exogenous glucocorticoid for 28 weeks, and one for 28 months (end of reported observation).[80] A further study used the B-lymphocyte–depleting agent rituximab and 12 weeks of depot ACTH 1–24 in 13 PAI patients. Ten of these patients had detectable cortisol at study entry (peak 26–265 nmol/L), and 54% had higher cortisol responses, but no patient achieved a normal response to ACTH.[81] Although these studies do not point to regenerative therapies being clinically viable at present, they suggest that a form of regenerative therapy with immune modulation may control Addison disease in the future.

Finally, PAI may respond to cell-based replacement therapies designed to replace adrenocortical cells. Most PAI cases are autoimmune; hence, such therapies would be most applicable in already immunosuppressed individuals such as those who have had a renal transplant[82-84] or if the adrenal cell allograft was provided in an encapsulated form where the immune system can be excluded, obviating the need for immunosuppression—this has been done in animal models, such as a xenograft model in rats.[85]

Future Directions and Novel Therapies, 1585
Conclusion, 1586

The adrenal cortex, a steroid hormone-producing gland, is made up of three distinct functional zones. The outermost zona glomerulosa produces mineralocorticoids, principally aldosterone, that are responsible for sodium and fluid balance. Aldosterone is secreted in response to stimulation from the renin-angiotensin axis and ambient potassium levels. The zona fasciculata produces glucocorticoids, in humans, mainly cortisol, which is required to maintain glucose homeostasis and vascular tone. Adrenocorticotropic hormone (ACTH) is the main regulator of cortisol synthesis. The innermost zona reticularis produces sex steroids, mainly androgen precursors that support secondary sexual characteristics, such as pubic hair. The regulation of the latter class of steroids is less well understood, but they are also ACTH-responsive. A more detailed discussion of basic adrenal anatomy and physiology may be found in Chapters 85–90.

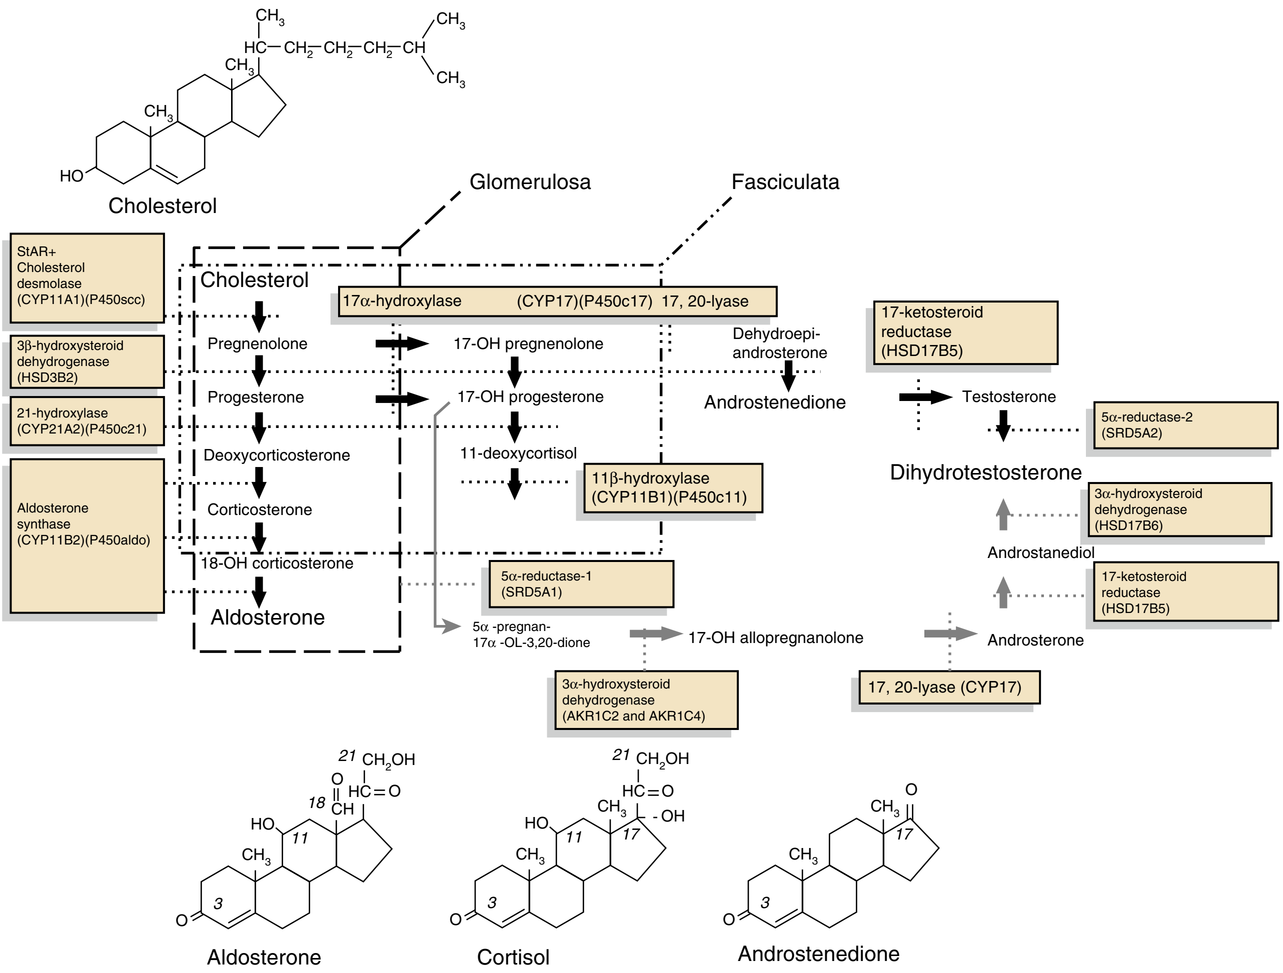
This chapter will address several disorders of adrenal steroidogenesis resulting in overproduction or underproduction of these corticosteroids, depending on the enzymatic defect. The key first step in synthesis of all steroids is importing cholesterol from the outer to the inner mitochondrial membrane, facilitated by steroidogenic acute regulatory protein (StAR).[1] The side chain of cholesterol is then cleaved to yield pregnenolone. A series of enzymatic reactions thereafter lead to aldosterone, cortisol, or androstenedione, representing the three major categories of adrenal cortical products (Fig. 94.1).

The most common adrenal steroidogenic defects are enzymatic deficiencies affecting cortisol production, collectively referred to as *congenital adrenal hyperplasia* (CAH). All are transmitted as autosomal recessive traits. Impaired cortisol synthesis leads to chronic elevation of ACTH via loss of the negative feedback inhibition of the hypothalamic–pituitary–adrenal (HPA) axis. This overstimulation of the adrenal cortex by ACTH results in adrenal hyperplasia. Specific forms of CAH are identified by the abnormal patterns of glucocorticoid, mineralocorticoid, and sex steroid secretion, and by accompanying clinical manifestations, including genital atypia, disturbances in sodium homeostasis and blood pressure regulation, and the postnatal consequences of sex steroid imbalance affecting somatic growth and fertility. A summary of the clinical, hormonal, and genetic features of these steroidogenic defects appears in Tables 94.1 to 94.3.

The different types of CAH may be divided into virilizing and nonvirilizing disorders. In the first group of enzyme deficiencies, sex steroids, especially androgen precursors, are overproduced. Affected 46,XX newborns are often identified by genital atypia. Newborn screening for the most common form of CAH caused by 21-hydroxylase deficiency (21-OHD) has resulted in expedited diagnosis and treatment. Screening programs have greatly reduced the incidence of late diagnosis and progressive signs of androgen excess in patients of either sex. In nonvirilizing forms of CAH, 46,XY individuals show incomplete genital development. Additional nongenital phenotypic abnormalities may be present in most types of CAH, including musculoskeletal, cardiovascular, and metabolic problems. Individualized treatment is required to optimize overall health and quality of life.

KEY POINTS

- The adrenal gland produces glucocorticoids, mineralocorticoids, and sex steroids.
- The most common defects of adrenal steroidogenesis are due to autosomal recessive enzymatic deficiencies affecting cortisol production, collectively referred to as congenital adrenal hyperplasia (CAH).
- Cortisol deficiency results in elevation of adrenocorticotropic hormone (ACTH), and chronic ACTH stimulation of the adrenal glands results in abnormal patterns of glucocorticoid, mineralocorticoid, and sex steroid secretion.
- The clinical manifestation of CAH is closely related to the type and severity of the impairment, with types divided into two major categories: virilizing and nonvirilizing forms.



Cholesterol
Glomerulosa
Fasciculata
StAR+ Cholesterol desmolase (CYP11A1)(P450scc)
3β-hydroxysteroid dehydrogenase (HSD3B2)
21-hydroxylase (CYP21A2)(P450c21)
Aldosterone synthase (CYP11B2)(P450aldo)
Cholesterol
Pregnenolone
Progesterone
Deoxycorticosterone
Corticosterone
18-OH corticosterone
Aldosterone
17α-hydroxylase (CYP17)(P450c17) 17, 20-lyase
17-OH pregnenolone
17-OH progesterone
11-deoxycortisol
11β-hydroxylase (CYP11B1)(P450c11)
Dehydroepi-androsterone
Androstenedione
17-ketosteroid reductase (HSD17B5)
Testosterone
5α-reductase-2 (SRD5A2)
Dihydrotestosterone
3α-hydroxysteroid dehydrogenase (HSD17B6)
Androstanediol
17-ketosteroid reductase (HSD17B5)
Androsterone
5α-reductase-1 (SRD5A1)
5α -pregnan-17α -OL-3,20-dione
17-OH allopregnanolone
3α-hydroxysteroid dehydrogenase (AKR1C2 and AKR1C4)
17, 20-lyase (CYP17)
Aldosterone
Cortisol
Androstenedione

Fig. 94.1 Adrenal steroidogenesis. Biosynthetic steps occurring in the zonae glomerulosa and fasciculata are indicated. Enzymes are boxed with dotted lines extending to arrows denoting each enzymatic conversion; two enzymes, CYP11B2 and CYP17, catalyze several successive enzymatic conversions. Planar structures of cholesterol, aldosterone, cortisol, and androstenedione are illustrated. Additional conversions inside and outside the adrenal cortex generate more potent androgens such as testosterone, dihydrotestosterone, and 11-oxo androgens. The "backdoor," or alternative, pathway from 17-OH progesterone to dihydrotestosterone is illustrated, with the involved intermediates and enzymes printing in italics (also see Chapter 87).

TABLE 94.1 Genetic Causes and Clinical Features of the Various Forms of Congenital Adrenal Hyperplasia

Type of CAH	21-Hydroxylase Deficiency	11β-Hydroxylase Deficiency	17α-Hydroxylase/17,20-Lyase Deficiency	3β-Hydroxy-Steroid Dehydrogenase Type 2 Deficiency	P450 Oxido-reductase Deficiency	Lipoid Adrenal Hyperplasia	Cholesterol Side Chain Cleavage Enzyme Deficiency

TABLE 94.3 Steroid profiles in Congenital Adrenal Hyperplasia (CAH)

Type/Enzyme	Cosyntropin stimulation testing*	Other Testing
21-hydroxylase deficiency		
Classic	17-OHP generally >10,000 ng/dL (150 nmol/L)	
Nonclassic	17OHP >1000 ng/dL (30 nmol/L)	Early-morning follicular phase serum 17OHP <200 ng/dL (<6 nmol/L) excludes NC CAH
11β-hydroxylase deficiency	11-deoxycortisol generally >3500 ng/dL for classic and >twice normal for NC	
17α-hydroxylase/17,20-lyase deficiency	Poor response of 17OHPreg and 17OHP Elevated ratio of: DOC/cortisol, corticosterone/sex steroids	
3β-hydroxysteroid dehydrogenase type 2 deficiency	17OHPreg >6600 ng/dL (200 nmol/L) Markedly elevated ratios 17OHPreg/cortisol (generally >180 basal and >480 stimulated)	Poor testosterone response hCG stimulation in infancy
P450 oxidoreductase deficiency	Variable 17OHP response, variable cortisol response (often inadequate)	Urine or serum steroid metabolite profile shows evidence of both 21-hydroxylase and 17-hydroxylase deficiencies¥
Lipoid adrenal hyperplasia or SCC enzyme deficiency	Minimal to no response NC: variable response, ↓cortisol common	Classic: Minimal response hCG stimulation Genetic testing needed to differentiate lipoid CAH and SCC deficiency

*Administration of standard dose of 250 mcg cosyntropin with serum hormone levels measured at 60 min.

¥Urine: Ratio of progesterone metabolite pregnanediol over cortisol metabolites (tetrahydrocortisone [THE] + tetrahydrocortisol [THF] + 5αTHF) is elevated.[56]

NC, Nonclassic; *17OHP*, 17-hydroxyprogesterone; *DHEA*, dehydroepiandrosterone; *DOC*, deoxycorticosterone; *17OHPreg*, 17-hydroxypregnenolone; *hCG*, human chorionic gonadotropin; *SCC*, side chain cleavage.

VIRILIZING FORMS OF CONGENITAL ADRENAL HYPERPLASIA

21-Hydroxylase Deficiency

Approximately 90% to 95% of cases of CAH are caused by 21-OHD.[2] The literature has historically described classic and nonclassic forms of this disorder, although current thinking views *CYP21A2* allelic variants and their phenotypic manifestations as a continuum. The classic form is defined by significantly reduced enzyme activity with impaired cortisol production manifesting clinically at birth. Nonclassic forms are caused by less severe enzyme defects, and symptoms are generally milder with absence of genital atypia in affected female newborns.

Clinical Features of Classic 21-Hydroxylase Deficiency. This is the most common cause of atypical external genital development in 46,XX individuals. The prevalence ranges from approximately 1 in 14,000 to 1 in 18,000 live births in most countries that undertake screening, with higher prevalence in regions with consanguineous families.[3] The higher disease prevalence among inbred populations is attributable to the fact that all adrenal steroidogenic enzyme deficiencies are inherited by autosomal recessive transmission, and inbred populations promote propagation of pathogenic alleles by so-called founder effects.

Adrenal steroid 21-hydroxylase (CYP21, P450c21) is required for both glucocorticoid and mineralocorticoid production. It accepts electrons from an NADPH-dependent P450 oxidoreductase (POR; see later) and converts 17-hydroxyprogesterone (17-OHP) to 11-deoxycortisol and progesterone to deoxycorticosterone (DOC), respective precursors for cortisol and aldosterone. When this enzyme is defective, insufficient negative feedback by cortisol stimulates ACTH secretion, causing adrenal hyperplasia with diversion of precursor steroids to the sex hormone pathway, which does not require 21-hydroxylase. Surplus androgens produced in this manner virilize 46,XX fetuses' external genitalia (Fig. 94.1).

Gonadal differentiation proceeds normally during gestation. Because there are no testes to secrete anti-Müllerian hormone, Müllerian duct development in the affected female is also normal, forming the uterus and fallopian tubes. A urogenital sinus, consisting of a conjoined urethra and vagina, may originate near the uterus or more distally just proximal to the perineum. The clitoris is enlarged to a variable degree at birth and may be indistinguishable from a penis. The urethral meatus may open on the peritoneum, on the shaft of the phallus, or rarely at the tip of the glans in the normal male position. Descriptive scoring systems have been developed to characterize genital appearance[4] (Fig. 94.2). With normal ovaries and uterus, childbearing potential exists in females, even though their external genitalia are virilized.

Wolffian duct differentiation is normal in males but generally absent in females, as ductal development in males is supported in a paracrine manner by testosterone secreted by the testes. Elevated systemic levels of adrenal androgens are not usually adequate to support this process. Penile size is normal in newborn males with CAH. However, both males and females who are not diagnosed and treated continuously from early infancy can undergo progressive virilization of the external genitalia.

In approximately 75% of cases, males and females with this enzyme deficiency not only suffer from cortisol deficiency, but also synthesize insufficient aldosterone to maintain sodium homeostasis. Before the era of near-universal newborn screening, infants with this severe, "salt-wasting" type of CAH, especially males who lacked the physical signs of genital ambiguity, often presented with failure to thrive culminating in hypovolemic shock with hypoglycemia, hyponatremia, and hyperkalemia, termed salt-wasting adrenal crisis. Hyperpigmentation of the scrotum, areola, and mucus membranes may be present but is not a reliable diagnostic sign. The remaining 25% of classic CAH-affected infants produce slightly more cortisol and aldosterone, are less likely to suffer acute episodes of adrenal insufficiency, and are said to have "simple virilizing" disease. Such patients may nevertheless benefit from

low-dose mineralocorticoid treatment in addition to standard glucocorticoid replacement (see later), especially early in life due to relative renal tubular resistance to the salt-retaining effects of aldosterone in early infancy and the low sodium content of infant diets.

Growth Sequelae. Sequelae of adrenal sex hormone excess are recognized in CAH patients, but in some cases are difficult to differentiate from the adverse effects of chronic exogenous glucocorticoid therapy.[5] First among these complications in children are perturbations of growth and puberty. A systematic review and metaanalysis for over 1000 patients showed adult height to be somewhat shorter than average for midparental heights (-1.03 standard deviations, corresponding to ~7 cm).[6] Many of these published reports were based on children diagnosed clinically before implementation of newborn screening, with its resultant early initiation of treatment. Since this degree of height compromise is compatible with short normal stature in many cases, growth-enhancing drugs have not been incorporated into standard practice guidelines.[3] Patients who are not diagnosed early and treated may experience rapid somatic growth and bone maturation, with precocious pubarche. Prevention of hyperandrogenism is important, and early diagnosis and treatment of classic 21-OHD have been associated with improved height outcomes compared with those diagnosed late.[7] If there is marked bone age advancement compared with chronologic age, central precocious puberty may ensue, prompting the need for gonadotropin releasing hormone analog (GnRHa) therapy. Such treatment is not recommended for patients with less than or equal to 2 standard deviations bone age readings and no clinical signs of precocious puberty, nor would GnRHa be effective in patients at or near adult height. There have been few long-term controlled clinical trials of puberty-modulating therapies in CAH, discussed in further detail later.

Reproductive Function. In adolescents and young adults, concerns about pubertal, sexual, and reproductive function are prominent. In addition to precocious puberty, elevated levels of adrenal sex hormones interfere with the hypothalamic–pituitary–gonadal axis. Young women with well-controlled CAH usually experience normal menarche.[8] Those whose condition is less well-controlled often experience acne, female hirsutism, male pattern hair loss, altered body habitus, irregular menses, and ultimately decreased fertility.[9] In up to 50% of poorly controlled males, benign testicular adrenal rest tumors (TARTs) may be detected on ultrasound, or rarely by palpation.[10] Adrenal rest tissue is thought to originate from ether ACTH-stimulated gonadal progenitors or aberrant cells of adrenocortical origin that migrate with primitive gonadal cells during fetal development when the adrenal and gonadal cells separate from the urogenital ridge. Although most commonly found in the testes, adrenal rest tumors have been described in the ovaries, broad ligament, and other locations as well.[11] TARTs are usually bilateral and arise from the rete testes, and if such tumors expand, normal testicular parenchyma can be replaced, impairing testosterone production and causing oligospermia. Treatment for these issues is discussed later.

Screening by testicular ultrasound should begin in adolescence when first appearance often occurs. Optimization of glucocorticoid therapy can shrink TARTs and prevent progressive enlargement and eventual infertility; however, nonreversible fibrotic changes can occur with time. Semen cryopreservation could be offered to patients with TARTs, because irreversible testicular damage may occur. Surgery can be used to treat orchialgia when large masses are present, but has not been able to restore fertility.[12]

Metabolic Sequelae. Alterations in the metabolome are seen in CAH patients treated with glucocorticoids.[13] Conceivably, such changes may mediate some of the long-term adverse outcomes in this disease. Both children and adults are prone to overweight and obesity. Cardiovascular changes including elevated blood pressure and increased carotid intimal thickness have been detected even in the pediatric population, progressing in frequency among adults (reviewed in[14]).

Counseling about healthy lifestyle choices and early attention to cardiometabolic risk factors is indicated in patients receiving chronic glucocorticoid therapy. A metaanalysis of 20 studies of cardiovascular risk factors in glucocorticoid treated patients with CAH found higher prevalence of increased blood pressure, insulin resistance, and carotid intima thickness compared with controls.[14] Furthermore, a Swedish national cohort study of 588 patients with CAH showed an increased prevalence of hypertension, hyperlipidemia, diabetes, and venous thromboembolism in adults with classic CAH compared with controls.[15]

Bone Health. Endogenous adrenal sex hormone excess and exogenous glucocorticoid exposure represent competing influences on bone mineral accrual. A large retrospective European multicenter survey indicated that higher glucocorticoid doses were correlated with low bone density among young women, but fractures were infrequent.[16] The authors concluded that CAH patients may be at increased risk for osteopenia and osteoporosis later in life.

Overall, adults with 21-OHD have lower bone mineral density than control populations, with the prevalence of osteoporosis or osteopenia ranging from 37% to 81%,[17,18] and few studies report increased fracture rate.[19]

Mental Health. With respect to cognitive function, a relatively large and well-controlled Swedish study showed that patients with CAH generally have normal intelligence but may have discretely impaired executive functions.[20] Severe salt-wasting disease with null CAH genotypes was associated with poorer general cognitive capacity. Behavioral investigations point to male-pattern behaviors in 46,XX individuals, although gender identity is largely female.[21,22] Anxiety and emotional problems were no different in children affected with CAH compared with controls,[23] but higher prevalence of anxiety, depression, and alcohol misuse compared with controls were reported in adults in population-based studies.[23-25] Differences have been identified in brain structure relating to visuospatial and memory task performance in young adult CAH patients.[26] Patients who had antenatal exposure to dexamethasone in the first trimester not only showed alterations in brain structure but also had epigenetic changes reflected in altered gene methylation patterns.[27]

Quality of life in adults has been studied extensively; however, results are far from uniform (reviewed in[3]). As with many chronic illnesses, multiple factors determine mental health and social functioning. Although hormonal influences may contribute to mental health, sexual well-being, especially in females born with atypical genitalia, is a key element affecting quality of life. Nonetheless, most are heterosexual and do not have gender identity disorders.[28,29]

Clinical Features of Nonclassic 21-Hydroxylase Deficiency. In the typical nonclassic patient, cortisol and aldosterone insufficiency are subclinical, and androgen excess is less apparent compared with the classic patient.[30] This form of CAH is quite common, but seldom presents in the newborn period and is not the primary target of newborn screening programs, hence the alternative term “late-onset” CAH. The estimated prevalence is approximately 1 in 200 in the White American population.[31] Beyond the newborn period, progressive virilization may be observed in young children, associated with unusually rapid growth, axillary or pubic hair development, acne, and radiographic evidence of accelerated skeletal maturation. The most common clinical presentation is an adolescent or young adult woman with hirsutism, oligomenorrhea, severe acne, and subfertility.[32] Adolescent and adult males, if they are clinically identified, may have severe acne. Rare individuals with nonclassic CAH have been reported with TARTs.[33] In those instances, the *CYP21A2* genotype included one Pro-30-Leu allele, intermediate in severity between nonclassic and classic forms of CAH. Similarly, subfertility is rare in men with nonclassic CAH. A retrospective survey of over 200 Israeli adult men with abnormal sperm analysis found no cases of nonclassic CAH based on cosyntropin stimulation tests.[34] A separate Swedish population-based cohort analysis found no evidence of infertility in young men with nonclassic CAH, although classic CAH was associated with male infertility.[35]

Frank evidence of hypovolemic shock does not usually occur in individuals with nonclassic CAH, unless chronically treated with glucocorticoids, subjected to severe stress (e.g., surgery, febrile illness, or prolonged gastroenteritis), and deprived of sufficient glucocorticoid

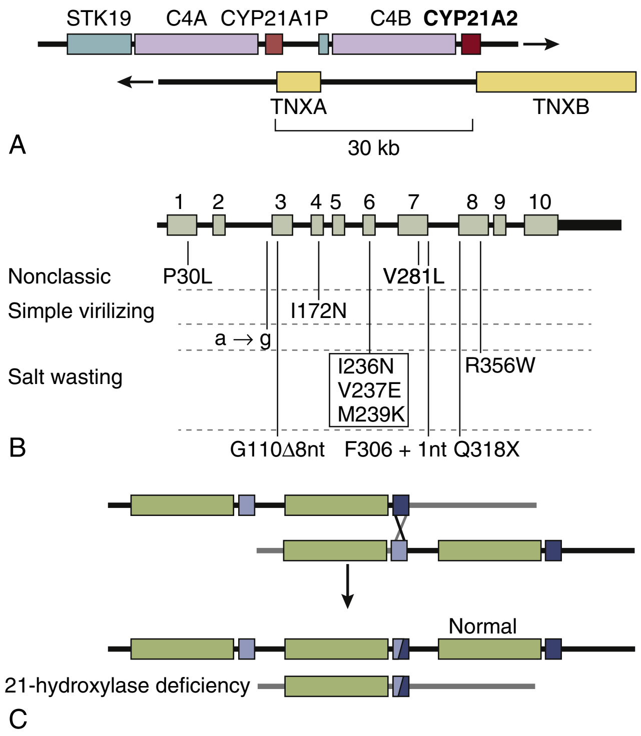

Fig. 94.3 The *CYP21* genes. **A,** The genetic region on chromosome 6p21.3. The genes are described in text, and a 30,000-base pair (30-kb) scale is included. **B,** Structure of the *CYP21* genes. Exons are numbered. Mutations affecting enzymatic function that are normally present in the *CYP21A1P* pseudogene are shown. They are positioned vertically to show the severity of congenital adrenal hyperplasia they cause when transferred to *CYP21A2* in gene conversion events. **C,** An illustration of unequal meiotic crossing-over generating a deletion representing a salt-wasting 21-hydroxylase deficiency allele. The other chromosome has three copies of the tandem and is not associated with disease. For simplicity, only the *C4* and *CYP21* genes are illustrated.

replacement. To our knowledge, there are no cases of previously untreated patients with nonclassic CAH experiencing an adrenal crisis. Additionally, hyperandrogenic signs and symptoms are much more variable and often subtle, such that many individuals diagnosed with nonclassic CAH can avoid glucocorticoid treatment or be treated only when symptomatic. The treatment of CAH is discussed in more detail below.

Molecular Genetics. The 21-hydroxylase enzyme (CYP21, P450c21) is a microsomal cytochrome P450 enzyme (i.e., it is located in the endoplasmic reticulum). Its expression is regulated by trophic stimuli, including ACTH in the zona fasciculata and angiotensin II in the zona glomerulosa (see Chapter 87). The structural gene encoding CYP21, *CYP21A2,* is located on the short arm of chromosome 6 (6p21.3), within a 30-kb tandem duplication (Fig. 94.3) that includes a highly homologous pseudogene, *CYP21A1P.*[2] The duplicated region also contains the *C4B* and *C4A* genes, encoding two isoforms of the fourth component of serum complement, and a small part of *STK19,* which encodes a serine-threonine kinase. On the opposite DNA strand, this region contains part of the *TNXB* gene and the *TNXA* gene, which encode tenascin-X, a connective tissue protein, which, when deleted or mutated, causes hypermobility-type Ehlers–Danlos syndrome (EDS).[36] The combination of CAH and EDS, termed CAH-X syndrome, is due to a contiguous gene deletion and is found in 10% to 15% of CAH patients.[37,38]

The nucleotide sequences of *CYP21A2* and *CYP21A1P* are 98% identical in exons and approximately 96% identical in introns, but *CYP21A1P* carries 10 mutations that prevent synthesis of a functional enzyme, including frameshifts, nonsense (stop codon) and missense (amino acid substitutions) mutations, and mutations affecting splicing of pre-mRNA. Approximately 90% to 95% of 21-OHD alleles are the result of homologous recombination events between *CYP21A2* and *CYP21A1P*. During meiosis, misalignment of homologous chromosomes leads to unequal crossing over, resulting in 30-kb deletions. If the breakpoint of the crossover is within *CYP21A2*, this will prevent synthesis of a functional enzyme. Deletions account for approximately 20% of mutant alleles in most populations. Gene conversion can result from mitotic or meiotic events that transfer one or more mutations normally present in *CYP21A1P* to *CYP21A2*. In general, the functional consequence of each DNA alteration corresponds with the clinical severity of the inherited disorder. Therefore, *CYP21A2* mutations are classified into three general groups in descending order of enzymatic compromise. Deletions, nonsense mutations, frameshifts, and missense mutations that totally abolish enzymatic activity are salt-wasting classic alleles, comprising mutation group A (divided in some analyses into “null” and group A categories). A single-nucleotide mutation that alters splicing of intron 2 (“intron 2 G” mutation) is particularly common, comprising approximately 25% of mutant alleles in most populations. It has been seen in both salt-wasting and simple virilizing patients, suggesting that there is a small amount of normally-spliced mRNA; it is sometimes considered the only member of “mutation group A2.” A nonconservative amino acid substitution, isoleucine-172 to asparagine (I172N), has been associated with the simple virilizing form of the disorder. It reduces enzymatic activity to approximately 1% of normal (mutation group B). Finally, missense mutations such as valine-281 to leucine (V281L) and proline-30 to leucine (P30L) reduce enzyme activity to approximately 20% to 50% of normal (mutation group C) and are associated with nonclassic disease. Although enzyme function *in vitro* appears to be similar,[39] clinical observations suggest that patients carrying the P30L allele are somewhat more symptomatic, straddling the border between simple virilizing and nonclassic forms of CAH.[40] In addition to alleles arising from deletions or gene conversions, there are at least 230 other mutations causing 21-OHD, and close to 700 additional sequence variants of unknown significance have been reported.[41] Because 21-OHD is a recessive disorder, the phenotype of each patient can generally be predicted from the less severely affected allele; e.g., a patient carrying a group A mutation (null enzyme activity) on one allele and a group C mutation (partial enzyme impairment) on the other will usually have nonclassic disease. Nevertheless, such compound heterozygotes may have a somewhat more severe phenotype than patients carrying two group C alleles.[40,42,43]

It is not well understood how other factors—such as individual polymorphisms in the androgen receptor or variations in the activities of other enzymes required for metabolism of steroid precursors—influence phenotype.

Diagnosis of 21-Hydroxylase Deficiency. CAH owing to 21-OHD is diagnosed on the basis of 1) clinical findings, 2) biochemical and hormonal measurements, and 3) when necessary, genotyping *CYP21A2* to identify disease-specific mutations. Phenotypic features have been discussed above. Hormone levels in blood or urine can establish the diagnosis of an enzyme defect by demonstrating an increased precursor-to-product ratio. In classic 21-OHD CAH, serum cortisol levels are usually low to low-normal, inappropriate for the markedly elevated levels of ACTH and 17-OHP; moreover, cortisol measurements by immunoassay may be falsely normal, rather than low, owing to cross-reaction with 21-deoxycortisol. The latter steroid has been suggested as a possible diagnostic alternative to measuring 17-OHP.[44] The typical analyte used for diagnosis of CAH is blood or serum 17-OHP, the primary substrate for 21-hydroxylase, most accurately measured by liquid chromatography followed by liquid chromatography tandem mass spectrometry (LC-MS/MS).

The standard confirmatory diagnostic procedure for all forms of CAH is the 60-minute cosyntropin (ACTH 1–24) stimulation test, generally done after the first 24 to 48 hours of life, or later in very small infants. Blood is drawn before and then 60 minutes after intravenous or intramuscular injection of a supraphysiologic 0.25-mg bolus of ACTH; in low-birth weight, premature infants, the dose may be reduced to 0.125 mg. Hormonal diagnosis should be correlated with clinical and genetic findings. Clinicians should be aware that blood filter paper and serum measurements for 17-OHP are not directly comparable. Ideally, a full adrenal cortical hormone profile should be obtained to exclude other types of CAH; such profiles are available in endocrine specialty laboratories. Aldosterone, plasma renin activity (PRA), serum electrolytes, and glucose should also be measured. Newborns often have elevated levels of PRA, relative hyponatremia, and mild hyperkalemia due to renal immaturity,[45] making it challenging to identify infants as having permanent salt-wasting CAH as opposed to more transient abnormalities of electrolyte homeostasis.

Patients with classic CAH usually have markedly elevated baseline levels of 17-OHP, and treatment of a critically ill infant should not be delayed to perform cosyntropin stimulation testing. In nonclassic CAH, because of diurnal variation beyond infancy, random measurements of baseline serum 17-OHP may be normal. If one obtains early morning (8:00 a.m.) samples, 17-OHP levels are more likely to be elevated. Confirmation of nonclassic CAH often requires cosyntropin stimulation; performing this test also permits evaluation of peak cortisol production and analysis of other adrenal steroids.

Blood levels of 17-OHP from heel-stick filter paper specimens, detected by automated immunoassays, form the basis for CAH newborn screening. Now conducted in all 50 states in the United States, as well as in many other countries, newborn screening has excellent sensitivity for classic CAH, markedly reducing the likelihood of salt-wasting crises owing to delayed diagnosis (especially in males). However, the positive predictive value is low (as low as 1% in many programs), leading to many recalls for retesting, particularly in premature, low-birth weight, or stressed neonates. The positive predictive value is improved by gestational-age adjusted cutoffs and second-tier screening using liquid chromatography followed by LC-MS/MS. Besides measurement of blood 17-OHP, additional data should be collected in the evaluation of a newborn with atypical genitalia potentially indicative of CAH. Karyotype along with fluorescence *in situ* hybridization for *SRY* is done to establish genetic sex. Pelvic and abdominal ultrasound can identify the presence or absence of the uterus, although the nature of gonadal tissue cannot be definitively ascertained by imaging. Because infants with atypical genitalia may also have renal malformations, the kidneys should also be examined by ultrasound.[46] The overall diagnostic approach to genital atypia is discussed in Chapter 101.

Molecular genetic analysis for *CYP21A2* gene mutations is widely available in commercial laboratories; however, it is important to first establish the diagnosis by hormone measurements. Because genotyping remains an expensive test with uncertain insurance reimbursement in the United States, and results are often not reported for several weeks, genotyping should not be the sole determinant for implementing and continuing medical management. Knowing the genotype cannot reliably determine phenotype and whether a given patient has a propensity to salt-wasting.

11β-Hydroxylase Deficiency

It was recognized by the early 1950s that rare patients with CAH develop hypertension rather than mineralocorticoid deficiency, and that the hypertension in such patients responds to glucocorticoid replacement. Most of these patients suffer from 11β-hydroxylase deficiency (11-OHD). This is perhaps the second or third most common form of CAH, comprising approximately 5% of cases or approximately 1 in 100,000 live births in most populations, but is more prevalent in North Africa and the Middle East.[47] Steroid 11β-hydroxylase activity is seen in the zona fasciculata and is required for conversion of 11-deoxycortisol to cortisol, and DOC to corticosterone.[48]

When these hormones are deficient, decreased production of cortisol and corticosterone reduces feedback inhibition on the hypothalamus and anterior pituitary, increasing secretion of ACTH. This stimulates the zona fasciculata of the adrenal cortex to overproduce steroid precursors proximal to the blocked 11β-hydroxylase step.

One of these precursors, DOC, is an active mineralocorticoid. Approximately two thirds of patients with the severe, "classic" form of 11-OHD have high blood pressure,[49,50] often beginning in the first few years of life. Although the hypertension is usually of mild to moderate severity, left ventricular hypertrophy and/or retinopathy have been observed in up to one third of patients, deaths from cerebrovascular accidents have been reported, and hypertensive nephropathy requiring renal transplantation may occur rarely. Other signs of mineralocorticoid excess such as hypokalemia and muscle weakness or paralysis occur in a minority of patients and are not well correlated with blood pressure. Plasma renin activity is usually suppressed in older children, and levels of aldosterone are consequently low, even though the ability to synthesize aldosterone is actually unimpaired.

Patients with 11-OHD often exhibit signs of androgen excess similar to those seen in 21-OHD. Affected females are born with some degree of masculinization of their external genitalia. This includes clitoromegaly and partial or complete fusion of the labioscrotal folds. The genitalia in affected 46,XX infants can be difficult to distinguish from those of a 46,XY cryptorchid infant.[49] Nevertheless, the gonads and the internal genital structures are normal, and affected 46,XX infants have reproductive potential.

As with 21-OHD, other signs of androgen excess that occur postnatally in both sexes include rapid somatic growth in childhood and accelerated skeletal maturation leading to premature closure of the epiphyses and short adult stature. Additionally, patients may have premature adrenarche and acne. Androgens may affect the hypothalamic–pituitary–gonadal axis, leading to amenorrhea or oligomenorrhea in females and true precocious puberty or, conversely, poor spermatogenesis in males.

Because severely affected infants with 11-OHD generally do not have salt wasting crises—in contrast to patients with 21-OHD—severely virilized females are less likely to be diagnosed early and are thus more likely to be raised as males than 21-OHD patients. This happened more frequently in the past, especially in regions with poor access to specialty medical care. Long-term sequelae of this disorder are similar to those described above for classic 21-OHD, including male infertility due to TARTs, although they are less thoroughly studied.

In addition to the classic form of this disorder, there exists a milder nonclassic type of 11-OHD, representing *CYP11B1* allelic variants, analogous to classic and nonclassic 21-OHD. Females with the nonclassic form of 11-OHD typically have normal genitalia at birth. With time they may develop hirsutism, acne, and primary or secondary amenorrhea. Children of both sexes with the nonclassic form of this condition have early pubarche, advanced bone maturation, and adult short stature. Hypertension is not a consistent feature of nonclassic 11-OHD.[51]

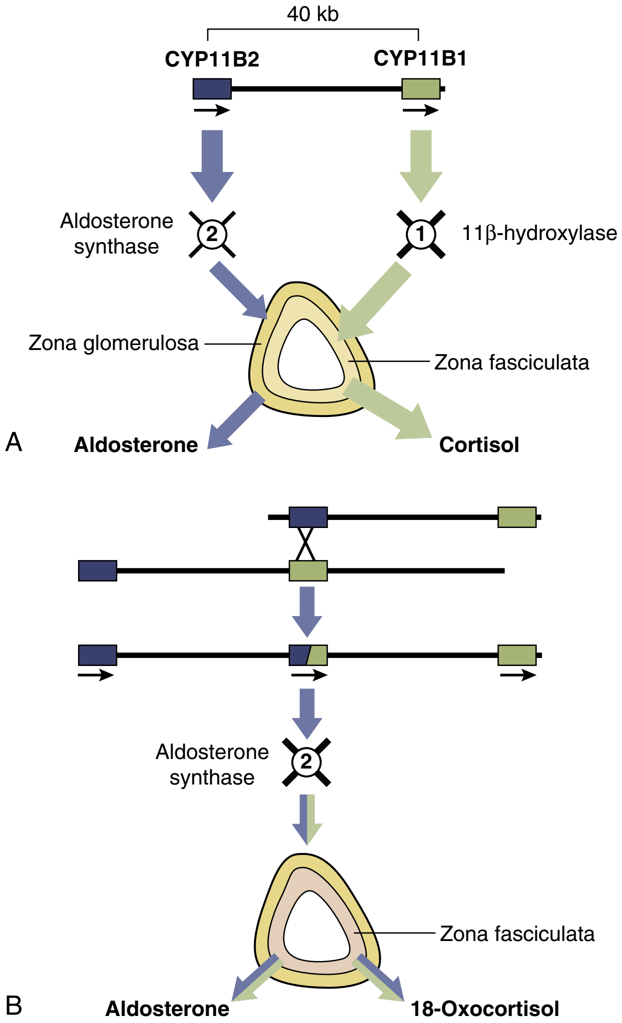

Fig. 94.4 The *CYP11B* genes, located on chromosome 8q24. A, *CYP11B2* and *CYP11B1* are expressed in the zonae glomerulosa and fasculata respectively; mutations in these genes cause aldosterone synthase and 11-hydroxylase deficiencies, respectively. B, Unequal crossing-over generates a chromosome with a 40-kb deletion (not shown) and another chromosome with three genes, the middle one of which has aldosterone synthase activity like CYP11B2 but is expressed in the zona fasciculata like CYP11B1. This causes glucocorticoid-remediable aldosteronism.

Physiology and Molecular Genetics. Humans have two 11β-hydroxylase isozymes that are respectively responsible for cortisol and aldosterone biosynthesis, CYP11B1 (P450c11) and CYP11B2 (P450aldo, P450c11AS) (Fig. 94.4). These isozymes, which are 93% identical in amino acid sequence, are mitochondrial cytochromes P450s located in the inner membrane on the matrix side. They accept electrons from an NAPDH-dependent electron-transport system consisting of two proteins, adrenodoxin reductase and adrenodoxin.

The CYP11B1 isozyme 11β-hydroxylates 11-deoxycortisol to cortisol. It can also convert DOC to either corticosterone (the predominant product) or 18-hydroxy,11-deoxycorticosterone, but it 18-hydroxylates corticosterone poorly. It cannot convert corticosterone into aldosterone. In contrast, CYP11B2 has somewhat weaker 11β-hydroxylase activity than CYP11B1, and it is normally expressed at much lower levels. Therefore, in general, "11β-hydroxylase" refers exclusively to CYP11B1. CYP11B2 can 18-hydroxylate and then 18-oxidize corticosterone to aldosterone, and is therefore commonly termed "aldosterone synthase." Old terminology refers to these latter conversions as being catalyzed by "corticosterone methyloxidase" I and II, respectively, but these terms are no longer useful, given that these reactions are catalyzed by a single enzyme.

CYP11B2 can also convert 11-deoxycortisol to 18-oxocortisol. This reaction normally does not occur at significant levels *in vivo* because CYP11B2 is not expressed in the zona fasciculata, but it becomes important in patients with glucocorticoid-suppressible hyperaldosteronism (see later).

In humans, CYP11B1 and CYP11B2 are encoded by two genes that are located 30 kb apart on chromosome 8q24.3. The coding sequences of these genes are 95% identical. *CYP11B2* is on the left (if the genes are pictured as being transcribed left to right). These genes are regulated in a manner consistent with their respective roles in cortisol and aldosterone biosynthesis; *CYP11B1* is expressed at high levels in normal adrenal glands that are appropriately regulated by ACTH.[52] *CYP11B2* is expressed only in the zona glomerulosa, and is regulated by angiotensin II and potassium levels (also see Chapter 88).

At least 100 mutations in *CYP11B1* have been identified in patients with classic 11-OHD.[53] In Moroccan Jews, a group that has a high prevalence of 11-OHD, almost all affected alleles carry the same mutation, arginine-448 to His (R448H).[54] This presumably represents a founder effect. This and most other missense mutations are in regions of known functional importance and severely inhibit enzymatic activity. Splice site, nonsense, or frameshift mutations also abolish enzymatic activity. Large deletions have rarely been reported, some of which are the products of unequal meiotic crossing-over with the adjacent *CYP11B2* gene, the same process that generates deletions in the *CYP21A2* gene causing 21-OHD. Each patient with mild, nonclassic disease carries at least one mutation that reduces (to ~10%–30% of normal) but does not destroy activity; the other mutation may be either mild or severe.

Although classic patients apparently completely or almost completely lack 11β-hydroxylase activity, they differ significantly in the severity of the various signs and symptoms of their disease. There is no strong correlation between severity of hypertension and biochemical parameters such as plasma levels of the 11β-hydroxylase substrates, deoxycortisol and DOC, or in urinary excretion of tetrahydrodeoxycortisol. Moreover, there is no consistent correlation between the severity of hypertension and degree of virilization.[55] These phenotypic variations must be governed by factors outside the *CYP11B1* locus.

Mutations in *CYP11B2* cause aldosterone synthase deficiency, and recombinations between *CYP11B1* and *CYP11B2* can result in glucocorticoid remediable aldosteronism; these conditions are discussed later in this chapter.

Diagnosis of 11β-Hydroxylase Deficiency. The basic diagnostic procedures are similar to those described for 21-OHD. The steroid profile for 11-OHD is distinctive for high levels of DOC and 11-deoxycortisol, as well as high levels of adrenal androgen metabolites. Because this enzyme deficiency inhibits steroid metabolism one step after steroid 21-hydroxylase, newborn screening may in some cases detect this type of CAH, as it can be associated with elevated 17-OHP levels. For most newborn screening programs, steroidogenic enzyme deficiencies other than 21-OHD CAH are not the primary targets. To differentiate 11-OHD from other types of CAH, detailed steroid profiling, usually in the context of a cosyntropin stimulation test, is performed (see earlier under Diagnosis of 21-Hydroxylase Deficiency). The serum electrolyte profile will occasionally show hypokalemia; plasma renin activity is suppressed in untreated patients. *CYP11B1* genotyping can aid in genetic counseling.

P450 Oxidoreductase Deficiency

POR is an electron donor for all cytochrome P450 enzymes in the endoplasmic reticulum. Thus, POR deficiency (PORD) affects CYP21 and CYP17 activity and presents with signs and symptoms that may resemble 21-OHD, 17α-hydroxylase/17,20 lyase deficiency, or a combination of the two enzyme deficiencies.[56,57] The precise prevalence of this condition is unknown but seems highest in Japan; over 100 cases have been reported in total. Most patients have normal baseline levels of cortisol, but mildly blunted responses to cosyntropin stimulation are frequently seen. Hypertension occasionally occurs, as more frequently happens in patients with 17-hydroxylase deficiency owing to CYP17 mutations. As with that disorder, hypertension is presumably a consequence of elevated levels of DOC resulting from impaired cortisol biosynthesis.

The clinical presentation of PORD usually includes disorders of sex development (DSD) in both XY and XX individuals, from minor degrees of undervirilization in males with micropenis or hypospadias to near-complete virilization of females. The latter fact seems paradoxical, because patients with actual mutations in CYP17 are unable to synthesize sex steroids. This difference arises because PORD preferentially inhibits the 17,20-lyase activity of CYP17, with 17-hydroxylase activity less affected. Thus, deficient 21-hydroxylase activity results in elevated 17-OH pregnenolone and 17-OH progesterone levels. Although, in contrast to 21-OHD, these are not efficiently converted to dehydroepiandrosterone (DHEA) and androstenedione because of low 17,20-lyase activity, 17-OH progesterone can be converted to the potent androgen, dihydrotestosterone, in a series of enzymatic reactions termed the "backdoor," or alternative, pathway[58] (Fig. 94.1; also see Chapter 87).

Maternal virilization has also been observed during pregnancy with a PORD fetus.[59] This is attributed to decreased activity of placental aromatase (CYP19), which is dependent on POR. Consequently, maternal screening reveals low serum and urine estriol.

A unique feature of PORD versus other forms of CAH, occurring in approximately 80% of cases, is a skeletal disorder known as Antley–Bixler syndrome.[57] This may affect the face (midface hypoplasia), cranium (craniosynostosis), hands and feet (arachnodactyly, talipes), large joints (radiohumeral synostosis), femurs (bowing, fractures), and other areas (e.g., scoliosis, pectus excavatum). It is probably a consequence of reduced activity of lanosterol 14α-demethylase (CYP51A1, a P450 enzyme required for cholesterol biosynthesis) and squalene monooxygenase (also called squalene epoxidase, a rate limiting enzyme for sterol biosynthesis), both of which are dependent on POR as an electron donor. The phenotype may also be influenced by abnormal levels of retinoic acid resulting from its reduced metabolism by CYP26 family isozymes.

It is possible to establish genotype–phenotype relationships because two mutations, arginine-457 to histidine (R457H) and alanine-287 to proline (A287P), occur relatively frequently (each represents ~25% of all mutant alleles, but the former is characteristically seen in Japanese patients). Patients have not been found with homozygous null mutations, which would presumably be lethal owing to abolition of activity of all P450 enzymes in the endoplasmic reticulum. Four genotype groups have been established: group B is comprised of patients homozygous for R457H; group C is R457H or A287P on one chromosome and any other missense mutation on the other; group D (the largest genotype group) is R457H or A287P on one chromosome and a null mutation on the other; group A comprises patients with any two other missense mutations. Skeletal malformations are seen in only 20% of patients in group A but invariably occur in group D.[56]

Maternal virilization is most often seen in the mothers of fetuses that carry R457H. In contrast, the R457H mutation is associated with less impaired cortisol secretion than other mutations.[60] These differences suggest that different missense mutations differentially affect molecular interactions with different P450 enzymes. The R457H mutation in POR may affect CYP17 (17-hydroxylase/17,20-lyase) less, resulting in more DHEA and androstenedione being synthesized, and decrease activity of CYP19 (aromatase) more, allowing these steroids to cross the placenta and virilize the mother. In contrast, glycine-539 to arginine (G539R) affects only the 17,20-lyase activity of CYP17A1, thus causing an isolated deficiency of sex hormones.

Diagnosis of P450 Oxidoreductase Deficiency. Diagnosis of PORD employs steroid profiling in urine samples by gas chromatography-mass spectrometry or LC-MS/MS in blood samples, which demonstrate high levels of pregnenolone, progesterone, and 17-OHP and decreased cortisol and androgen metabolites.[61] Nonetheless, PORD patients are seldom identified by newborn screening measuring 17-OHP. Genotyping of *POR* may be done once the hormonal diagnosis is confirmed.

3β-Hydroxysteroid Dehydrogenase Type 2 Deficiency

There are two homologous isozymes of 3β-hydroxysteroid dehydrogenase (3β-HSD).[62] Both oxidize the 3β-hydroxyl of the steroid to a ketone and isomerize the Δ^5 double bond to the Δ^4 position. Thus, the enzymes are formally termed *3β-HSD/*Δ^5>Δ^4 *isomerases*. The type 1 isozyme, encoded by the *HSD3B1* gene, is expressed in placenta and in peripheral tissues including small intestine, skin, colon, and liver. The type 2 isozyme, encoded by *HSD3B2,* is expressed in the adrenals and gonads. Mutations in the latter isozyme cause a rare form of CAH, accounting for less than 1% of cases, or less than 1:10^6 births.

In CAH due to 3β-HSD type 2 deficiency, steroid synthesis is blocked early in the pathway from cholesterol to end-products in both the adrenal cortex and gonads. The steroid profile is notable for elevated ratios of Δ^5 steroids (pregnenolone, 17-hydroxypregnenolone, DHEA) to Δ^4 steroids (progesterone, 17-OH progesterone, androstenedione) with relatively low levels of hormones dependent on this enzyme, including aldosterone, cortisol, and sex steroids. Salt-wasting adrenal crisis may occur and may be fatal if untreated. Male and female infants are born with variable degrees of genital atypia. XY individuals are incompletely masculinized owing to low levels of testosterone and dihydrotestosterone. The abnormalities typically involve the external genitalia (perineal hypospadias), but internal Wolffian structures (e.g., vas deferens) are unaffected. This is similar to findings in other disorders of androgen biosynthesis such as 17β-HSD type 3 (17-ketosteroid reductase) deficiency, as well as 5α-reductase type 2 deficiency. Despite low levels of sex steroid production, DHEA (itself not an active androgen) may be converted to more potent androgens via the unaffected 3β-HSD type 1 isozyme, causing mild virilization in girls. High levels of 17-hydroxypregnenolone may undergo extraadrenal conversion to 17-OHP, leading to positive results on newborn screening tests.[63]

Diagnosis of 3β-Hydroxysteroid Dehydrogenase Deficiency. The early diagnosis of 3β-HSD deficiency is somewhat less straightforward than other forms of CAH, unless frank salt-wasting and adrenal crisis are observed. It is rare, whereas hypospadias and cryptorchidism from other causes occur relatively frequently in newborn males, and affected females have only mildly virilized external genitalia.

Moreover, 3β-HSD type 2 activity is highly regulated and varies widely during development and childhood (also see Chapter 87). It is normally low during the second trimester of gestation, rises near the end of gestation (thus increasing fetal cortisol secretion, which helps to trigger parturition), remains high during childhood, and decreases at adrenarche (thus facilitating synthesis of adrenal androgens).[64] In light of these developmental changes in enzyme activity, premature infants may be misdiagnosed as having 3β-HSD type 2 deficiency, just as they are liable to fail the newborn screen for 21-OHD. Premature adrenarche in children represents a similar diagnostic pitfall. Moreover, there is a high frequency of elevated Δ^5/Δ^4-steroid ratios in women with hirsutism, but these are very rarely associated with mutations in *HSD3B2*.[62] It is therefore important to confirm the diagnosis by cosyntropin stimulation testing and genotyping *HSD3B2*.[65] Basal or ACTH-stimulated serum levels of 17-OH pregnenolone above 6600 ng/dL (200 nmol/L) raise suspicion for this diagnosis; detailed age-related hormonal diagnostic criteria, from newborns to adults, have been determined in genotype-confirmed cases.[66,67]

Molecular Genetics. The HSD3B1 and HSD3B2 genes are approximately 93% identical in amino acid sequence and are located in tandem 100 kb apart on chromosome 1p13.1. Humans also have five pseudogenes in the same genetic region; two are located between the two active genes. Although this genetic arrangement is reminiscent of the duplicated *CYP21A1P* and *CYP21A2* genes (recombinations between which cause the vast majority of 21-OHD alleles), recombinations between *HSD3B2* and the adjacent pseudogenes apparently do not generate 3β-HSD deficiency alleles (deletions or gene conversions), presumably reflecting differences in recombination frequencies in the different chromosomal regions in which these gene clusters are located.

Genotype and phenotype are generally highly correlated in cases of classic 3β-HSD type 2 deficiency.[62,68] No functional 3β-HSD type 2 enzyme is expressed in the adrenals and gonads of patients suffering from the severe salt-wasting form, either owing to null (nonsense or frameshift) mutations in *HSD3B2*, or missense mutations that completely destroy enzymatic activity. Non-salt-losing classic 3β-HSD type 2 deficiency results from missense mutations that impair enzyme activity but leave sufficient activity to prevent salt wasting. In many cases these mutations change the kinetic behavior of the enzyme, but some seem to affect protein stability. Individuals diagnosed with putative mild, "nonclassic" 3β-HSD deficiency rarely carry mutations in *HSD3B2,* and heterozygous carriers of *HSD3B2* mutations are asymptomatic.

KEY POINTS

- Mutations in adrenal steroidogenic pathway genes result in four types of virilizing forms of congenital adrenal hyperplasia (CAH): 21-hydroxylase deficiency (*CYP21A2* gene), 11β-hydroxylase deficiency (*CYP11B1* gene), P450 oxidoreductase deficiency (*POR* gene), and 3β-hydroxysteroid dehydrogenase deficiency (*3βHSD2* gene).
- 21-hydroxylase deficiency accounts for approximately 95% of cases of CAH and is the most common cause of 46,XX atypical genitalia.
- The clinical features of the virilizing forms of CAH include genital atypia, abnormal puberty and growth patterns, reduced fertility, and variable degrees of salt-wasting and hypertension, depending on the form.
- There is a continuum of disease severity and phenotypic variability that mostly correlates with genotype.
- Nonclassic 21-hydroxylase is common and can be subclinical, whereas nonclassic forms of the other types of virilizing CAH are rare.
- Diagnosis is based on clinical findings, biochemical and hormonal measurements, and, when necessary, genotyping.
- Newborn screening for 21-hydroxylase deficiency is in place in the United States and many other countries, is based on 17-hydroxyprogesterone level from a heel-stick filter paper specimen, and can sometimes detect other forms of virilizing CAH.

NONVIRILIZING FORMS OF CONGENITAL ADRENAL HYPERPLASIA

17α-Hydroxylase/17,20 Lyase Deficiency

The conversions of pregnenolone to 17-OH pregenolone, and progesterone to 17-OH progesterone, are catalyzed by the 17-hydroxylase activity of CYP17A1 (P450c17), a P450 enzyme in the endoplasmic reticulum. The 17,20-lyase activity of the same enzyme further catalyzes the conversion of 17-OH pregnenolone to dehydroepiandrosterone, an essential step for all sex steroid synthesis (the direct conversion of 17-OH progesterone to androstenedione is not efficiently catalyzed by the human enzyme, see Chapter 87). These reactions utilize electrons donated by POR. Efficient redox coupling of NADPH oxidation to the 17,20 lyase reaction also requires cytochrome b5.[69]

CAH caused by mutations in *CYP17A1* is thought to be either the second or third most common form of CAH, after 21-hydroxylase and 11β-hydroxylase deficiencies. The exact worldwide prevalence is unknown, but clusters of cases have been identified in several locales (see later).

Most cases have impaired activities of both 17α-hydroxylase and 17,20-lyase. Although these deficiencies impair cortisol biosynthesis, affected patients do not suffer from adrenal insufficiency, in contradistinction to the presentation of 21-OHD. This is because synthesis of corticosterone, which is not a 17-hydroxylated steroid, is unaffected. Corticosterone is a glucocorticoid agonist (indeed, it is the main glucocorticoid in rodents and birds, which do not express CYP17A1 in the adrenal gland), but it is considerably (~3-fold) less potent than cortisol because the lack of a 17-hydroxyl group weakens its ability to bind the human glucocorticoid receptor. Thus, much more corticosterone must be secreted in patients with CYP17A1 deficiency than normal cortisol secretion in unaffected individuals. This increases secretion of corticosterone precursors, particularly DOC. As discussed previously, DOC is a potent mineralocorticoid. As a consequence, and similar to 11-OHD, patients with 17α-hydroxylase/17,20 lyase deficiency (17-OHD) frequently suffer from sodium-sensitive, low-renin hypertension and hypokalemia.

In contrast to the virilizing forms of CAH, 17-OHD results in underdeveloped or atypical external genitalia in males and amenorrhea in females.[65,69] Both males and females fail to undergo normal pubertal development and have sparse pubic and body hair. Male gynecomastia, though incompletely explained, may occur due to testosterone deficiency, with consequent relative estrogen excess produced by alternative enzymatic pathways.[70]

Over 100 mutations in CYP17A1 have been identified in patients with combined 17-OHD. Particular mutations prevail in specific locales owing to founder effects. The first mutation characterized was a duplication of four nucleotides in proline-480 (P480Hfs) found in Dutch Frieslanders and in Canadian Mennonites originally from this region. In Brazil, 17-OHD may be the second most common cause of CAH after 21-OHD, owing to two mutations, arginine-362 to cysteine (R362C) and tryptophan-406 to arginine (W406R). In China, a frameshift involving tyrosine-329 (Y329Kfs) and a deletion of glutamate-487 through phenylalanine-489 (D487-F489del) account for approximately 60% and approximately 20% of mutant alleles, respectively, and histidine-373 to leucine (H373L) has been identified in Korean, Chinese, and Japanese patients.

Rarely, the 17,20-lyase activity of CYP17A1 is impaired, with 17-hydroxylase activity relatively or completely preserved. Such patients have isolated defects of sex steroid synthesis but do not have adrenal hyperplasia or hypertension. In some cases, this is the result of mutations that impair interactions of CYP17A1 with POR or cytochrome b5. Examples include arginine-347 to histidine or cysteine (R347H or R347C) and arginine-358 to glutamine (R358Q), which involve residues on the enzyme surface that dock with accessory proteins, and glutamate-305 to glycine (E305G) in the active site. Mutations in accessory proteins can produce the identical phenotype. These include the unusual POR mutation glycine-539 to arginine (G539R) (most POR mutations affect more P450 enzymes) and *CYB5A* (the gene for cytochrome b5) mutations tryptophan-27 to stop (W27X) and histidine-44 to leucine (H44L).

The steroid profile for 17-OHD is distinctive for high levels of DOC, corticosterone (and their 18-hydroxy metabolites), pregnenolone, and progesterone, as well as low levels of cortisol, androgen, and estrogen precursors. In addition to treatment with glucocorticoids, these patients require gender-specific sex hormone replacement therapy to support puberty. Hypertension unresponsive to glucocorticoid treatment often requires separate treatment in 17-OHD, as in 11-OHD.

Mild, nonclassic cases of 17-OHD appear to be quite rare but may be difficult to ascertain. Females with mild 17-OHD might have irregular menses or decreased fertility, whereas affected males might have mildly low testosterone levels with mildly elevated gonadotropins or perhaps oligospermia. One child with mild undervirilization, normal blood pressure, and biochemical evidence of partial 17-OHD was a compound heterozygote for a frameshift mutation in arginine-36 (R36fs) and a missense mutation, tryptophan-121 to arginine (W121R), which partially impairs enzymatic activity. One single-nucleotide polymorphism in *CYP17A1* (rs1004467) has been identified as a susceptibility allele for hypertension, but it does not change the coding region of the enzyme and is thus of uncertain functional significance.

Diagnosis of 17α-Hydroxylase/17,20 Lyase Deficiency

The diagnosis of 17-OHD depends on finding elevated precursor-to-product ratios with cosyntropin stimulation. In general, the diagnosis relies on high levels of DOC (>100 ng/dL [>3 nmol/L]) and corticosterone (>4000 ng/dL [>116 nmol/L]) with low cortisol (<5 mcg/dL [<138 nmol/L]), androgens, and estrogens. Progesterone is also elevated, while aldosterone and renin are suppressed.[71] Gonadotropins and corticotropin (ACTH) are elevated, even in children. A characteristic feature of lyase deficiency is an elevated ratio of 17-OHP/androstenedione (>50), with low levels of sex steroids. As with other types of CAH, genotyping may clarify the diagnosis when hormone measurements are inconclusive.

Lipoid Adrenal Hyperplasia and Side Chain Cleavage (CYP11A1) Deficiency

Lipoid congenital adrenal hyperplasia (LCAH) is a rare, severe form of CAH that affects conversion of cholesterol to pregnenolone and thus impairs synthesis of all adrenal and gonadal steroids.[72]

In classic patients, mineralocorticoid and glucocorticoid deficiencies can cause salt-wasting crises and vascular collapse. Patients may die in infancy. 46,XY males have female-appearing external genitalia, but no internal Müllerian structures. In older children, serum anti-Müllerian hormone and inhibin levels are low.[73] Karyotypic females have normal internal and external genital structures.

LCAH is caused by defects in the StAR protein,[74] which normally facilitates cholesterol transport from the outer to the inner mitochondrial membrane, where the side chain of cholesterol is cleaved to produce pregnenolone, catalyzed by the cholesterol side chain cleavage enzyme (cholesterol desmolase, CYP11A1, P450scc).[75]

Mutations in StAR affect steroidogenesis through two "hits." First, because importation of cholesterol into mitochondria is the rate-limiting step of steroidogenesis, deficient StAR activity directly impairs steroid biosynthesis in affected tissues by approximately 90%. Second, because cholesterol cannot be utilized, cholesteryl esters accumulate in lipid droplets and eventually induce apoptosis in steroidogenic cells. Prenatally these include cells of the adrenal cortex and testicular Leydig cells. However, ovaries do not synthesize steroids prenatally. Thus, affected 46,XX females can develop secondary sexual characteristics and even menstruate in adolescence, because ovarian theca and granulosa cells do not accumulate abnormal levels of lipids until they become hormonally active. There is a single dominant ovarian follicle during each menstrual cycle. Sufficient estrogen is produced by that follicle during the follicular phase of the menstrual cycle to maintain secondary sexual characteristics (and to trigger estrogen-withdrawal bleeding at the end of the cycle) but is usually insufficient to trigger ovulation, and progesterone secretion later in the cycle is blunted owing to accumulating intracellular lipids. Assisted reproductive technologies can sometimes facilitate fertility in such patients.

Steroidogenesis in the placenta is not dependent on StAR, and thus the placenta of a fetus with StAR deficiency is able to produce the progesterone and estrogen necessary to sustain the pregnancy.

Although still rare, LCAH occurs at a somewhat higher frequency—approximately 1 in 300,000—in Japanese and Korean patients, most of whom carry the same nonsense mutation, glutamine-258 to stop (Q258X). A characteristic mutation is also seen in Palestinian Arabs, arginine-182 to leucine (R182L).

A nonclassic form of LCAH is recognized, caused by mutations, particularly arginine-188 to cysteine (R188C), that retain 20% to 30% of normal activity. Patients typically experience the gradual onset of adrenal insufficiency between 2 and 4 years of age but may not present until they are middle-aged adults. Mineralocorticoid deficiency may be evident only as a mild elevation of renin activity in patients on a low-salt diet. Males have normal external genitalia but may have primary gonadal failure and azoospermia.[76]

Before the discovery of StAR, it was assumed that LCAH was caused by mutations in *CYP11A1* (encoding the actual side chain cleavage enzyme). *CYP11A1* mutations do indeed occur, albeit less frequently than *STAR* mutations. Most of the reported mutations do not completely destroy enzymatic activity, suggesting that *CYP11A1* null mutations tend to be lethal prenatally. The reason for this is that, unlike *STAR* mutations, *CYP11A1* mutations interfere with placental steroid synthesis. Miscarriages and preterm births have been reported. The phenotype is otherwise similar to that produced by *STAR* mutations, but without intracellular accumulation of lipid droplets. The nonclassic form of CYP11A1 deficiency has variable age of onset of adrenal insufficiency and a range of gonadal effects including 46,XY hypospadias, cryptorchidism, or normal male genitalia, but with eventual gonadal failure and azoospermia.[77]

CYP11A1 is a mitochondrial P450 enzyme (see Chapter 87), and like the CYP11B isozymes, it receives electrons from an NADPH-dependent transport chain consisting of adrenodoxin reductase and adrenodoxin. It might be predicted that mutations in either of these latter proteins would yield a phenotype similar to CYP11A1 deficiency, by analogy with POR mutations, which affect activity of "microsomal" P450 enzymes in the endoplasmic reticulum (see the section on P450 Oxidoreductase Deficiency). However, mutations in the genes encoding adrenodoxin reductase and adrenodoxin have not been detected, suggesting that they are lethal prenatally.[72]

Diagnosis of LCAH and side chain cleavage deficiencies: Patients with classic forms of LCAH and CYP11A deficiency fail to respond to acute or chronic stimulation with either ACTH or human chorionic gonadotropin. Due to deficiency of all adrenal and gonadal steroids, levels of ACTH, gonadotropins, and renin are elevated. Hypoglycemia, hyponatremia, and hyperkalemia may be observed. The diagnosis may be confirmed by sequence analysis of *STAR* and *CYP11A1*.

KEY POINTS

- The non-virilizing forms of congenital adrenal hyperplasia (CAH; 17α-hydroxylase/17,20-lyase deficiency, lipoid adrenal hyperplasia, and side chain cleavage enzyme deficiency) have sex steroid deficiency, resulting in underdeveloped or atypical external genitalia in 46,XY individuals and lack of normal pubertal development in both sexes.
- Unlike other forms of CAH, patients with 17α-hydroxylase/17,20-lyase deficiency do not suffer from adrenal insufficiency because corticosterone, a glucocorticoid agonist, is produced in excess.
- 17α-hydroxylase/17,20-lyase deficiency caused by mutations in *CYP17A1* is thought to be either the second or third most common form of CAH, with increased prevalence in various locations, including Brazil.
- Lipoid CAH, caused by mutations in the gene encoding steroidogenic acute regulatory protein, and deficiency of side chain cleavage enzyme encoded by the *CYP11A1* gene, have similar clinical and biochemical profiles, necessitating genotyping to distinguish between the two.
- A spectrum of phenotypes of the nonvirilizing forms of CAH have been described.

OTHER CONDITIONS AFFECTING ADRENAL STEROID SYNTHESIS

Aldosterone Synthase Deficiency

The most frequent defect of aldosterone biosynthesis is congenital adrenal hyperplasia due to steroid 21-OHD (see earlier). Signs of androgen excess are prominent in such patients. Rare patients have aldosterone deficiency in the context of entirely normal cortisol and sex steroid synthesis. This is most often caused by deficient activity of the aldosterone synthase enzyme (corticosterone methyloxidase, CYP11B2, P450aldo, P450c11AS, P450cmo). This mitochondrial P450 enzyme, expressed in the adrenal zona glomerulosa, catalyzes a series of three conversions: DOC to corticosterone, then to 18-hydroxycorticosterone, and finally, to aldosterone[48] (also see Chapter 88).

Mineralocorticoid deficiency leads to excessive sodium excretion and potassium retention in the renal distal tubule and cortical collecting duct, causing hyperkalemia, hyponatremia, and hypovolemia. The clinical presentation of aldosterone synthase deficiency varies with age.[78] Infants may develop signs and symptoms of mineralocorticoid deficiency at a few days to weeks of age. These include vomiting and dehydration leading to hypovolemia and, occasionally, frank shock. Serum sodium is usually in the range of 120 to 130 mEq/L, whereas serum potassium ranges from 6.0 to 8.5 mEq/L. Although fatalities have occurred, the morbidity of aldosterone synthase deficiency is usually not as severe as that engendered by the salt-wasting forms of congenital adrenal hyperplasia. This presumably reflects normal synthesis of DOC, corticosterone, and cortisol in aldosterone synthase deficiency, which ameliorate the development of hyponatremia and shock. Some children are diagnosed in early childhood with failure to thrive, anorexia, mild dehydration, and electrolyte abnormalities. Although electrolytes usually normalize by a few years of age (especially on the typical Western high-salt diet), growth retardation may persist throughout childhood. Adults are usually asymptomatic but occasionally tolerate severe salt loss less well than unaffected individuals. Plasma renin activity is markedly elevated in affected infants and young children, but it may be normal in adults.

Aldosterone synthase deficiency was previously divided into two subtypes termed corticosterone methyloxidase (i.e., aldosterone synthase) deficiency types I and II.[78] These syndromes have identical clinical features but differ in profiles of secreted steroids; thus, the distinction is not very useful clinically. Levels of DOC are increased, and urinary excretion of corticosterone metabolites is elevated in both type I and type II deficiencies relative to excretion of cortisol metabolites. Whereas excretion of 18-hydroxycorticosterone (the intermediate between corticosterone and aldosterone) is mildly decreased in type I deficiency, urinary and serum levels of this steroid are dramatically increased in patients with type II deficiency. Aldosterone and its metabolites are undetectable in patients with type I deficiency, whereas urinary excretion is mildly decreased in type II deficiency, and serum levels of aldosterone are usually within normal limits, particularly in older children and adults. Type II deficiency may thus be readily diagnosed by marked (often 100-fold) elevation of the ratio of 18-hydroxycorticosterone to aldosterone in either urine or serum; the ratio does not vary with age in affected individuals and may be the sole biochemical abnormality in adults. Indeed, asymptomatic adults have occasionally been ascertained in family studies because of this ratio. However, this ratio is not useful for diagnosis of type I deficiency, because the very low levels of aldosterone render it meaningless.[78]

Genetic Analysis. Patients with aldosterone synthase type I deficiency all carry mutations in *CYP11B2*, such as frameshift or nonsense mutations, or nonconservative missense mutations that destroy enzymatic activity.[79] The converse is not always true; some patients with such mutations may have type II deficiency.

Iranian Jewish patients with type II deficiency are all homozygous for two mutations, R181W and V386A.[80] Genetic studies suggest that 0.4% of normal 18-oxidase activity is not rate-limiting for aldosterone biosynthesis, but 0.2% is. This is consistent with CAH due to 21-OHD, in which patients hemizygous for the I172N mutation with approximately 1% of wild-type 21-hydroxylase activity are also able to synthesize normal amounts of aldosterone.

Some infants with isolated hyperreninemic hypoaldosteronism do not carry mutations in *CYP11B2.* In some male infants, this may represent adrenal hypoplasia congenita due to NR0B1 (DAX1) mutations, which sometimes presents with isolated hypoaldosteronism, with cortisol deficiency developing later[81,82] (also see Chapter 86). In other kindreds, this may imply the existence of a distinct inherited form of hyperreninemic hypoaldosteronism, which has been termed familial hyperreninemic hypoaldosteronism-2 (FHHA2), distinct from aldosterone synthase deficiency (thus termed FHHA1).[83]

Glucocorticoid-Remediable Aldosteronism

Glucocorticoid remediable aldosteronism (GRA; also called dexamethasone- or glucocorticoid-suppressible hyperaldosteronism) is a form of hypertension inherited in an autosomal dominant manner with high penetrance. It is characterized by moderate hypersecretion of aldosterone, suppressed plasma renin activity, and rapid reversal of these abnormalities after administration of glucocorticoids. This feature distinguishes it from other familial forms of primary aldosteronism.[84,85] The clinical hallmark of GRA is early-onset hypertension, even in infancy or early childhood, but usually prior to age 20 years. The family history is often notable for several similarly affected generations in a kindred, some of whom may have died before age 40 years with cerebrovascular accidents precipitated by hypertensive crisis. In general, the blood pressure is approximately 30 mm Hg higher than in unaffected family members. Thus, not all affected individuals actually have hypertension if family members otherwise have low blood pressure.[86]

All patients with glucocorticoid-suppressible hyperaldosteronism have the same type of mutation, a chromosome that carries three *CYP11B* genes instead of the normal two[87,88] (Fig. 94.4). The middle gene on this chromosome is a chimera, with 5′ and 3′ ends corresponding to *CYP11B1* (encoding 11β-hydroxylase) and *CYP11B2* (encoding aldosterone synthase), respectively. The chimeric disease-associated gene is flanked by normal *CYP11B2* and *CYP11B1* genes. The chimeric gene is regulated like *CYP11B1* (expressed at high levels in the zona fasciculata and regulated primarily by ACTH) because it has transcriptional regulatory sequences identical to those of *CYP11B1.* If the chimeric gene has enzymatic activity similar to that of *CYP11B2,* a single copy of such an abnormally regulated gene should be sufficient to cause the disorder, consistent with the known autosomal dominant mode of inheritance of this syndrome.

Hypokalemia occurs often but not invariably; it is exacerbated by thiazide diuretics. Chronic hypokalemia may lead to polyuria, nocturia, enuresis, and polydipsia. Muscle weakness and discomfort, intermittent paralysis, fatigue, and growth failure affect children with severe hypokalemia.

Serum pH and the carbon dioxide and sodium concentrations may be elevated, and the serum chloride and magnesium levels decreased. Serum levels of calcium are normal. Plasma levels of aldosterone may be normal or elevated. Aldosterone concentrations in 24-hour urine collections are always increased. Plasma levels of renin are consistently low. The ratio of plasma aldosterone concentration to renin activity is always high, and this represents a cost-effective screening test for primary aldosteronism.[89] However, both renin and aldosterone levels may vary by time of day, posture, and sodium intake, making it difficult to establish consistent reference ranges. Therefore, a consistent sampling protocol should be used—for example, midmorning after the patient has been sitting for 15 min. If possible, antihypertensive drugs or other medications that can affect aldosterone or renin secretion should be avoided for several weeks prior to testing, including diuretics, β-blockers, angiotensin-converting enzyme inhibitors, angiotensin receptor blockers, clonidine, and nonsteroidal antiinflammatory agents. Calcium channel blockers have smaller effects on the biochemical measurements.

Urinary and plasma levels of 18-oxocortisol and 18-hydroxycortisol—17-hydroxylated homologs of aldosterone and 18-hydroxycorticosterone, respectively—are markedly increased in GRA, and to a lesser extent in other forms of primary aldosteronism.[90] This is a consequence of chimeric gene expression in the zona fasciculata, where the same steroid molecule can be exposed to both 17-hydroxylase and aldosterone synthase activities.

GRA should be distinguished from other forms of primary aldosteronism, which are treated differently. An autosomal dominant pattern of inheritance should raise suspicion for GRA, which is diagnosed by dexamethasone suppression tests in conjunction with genotyping.

Smith–Lemli–Opitz Syndrome

Defects in sterol delta-7-reductase encoded by the *DHCR7* gene are responsible for Smith–Lemli–Optiz (SLO) syndrome. During gestation, low maternal estriol levels and decreased fetal movements may signal the diagnosis. The phenotype for this enzyme deficiency includes breech presentation, low birth weight, short stature, developmental delays, microcephaly, seizures, behavioral problems, ptosis, hypertelorism, cataracts, micrognathia, low-set ears, cleft palate, cardiac defects, hypoplastic lungs, intestinal malrotation, renal defects, skeletal defects (especially polydactyly), and varying degrees of undervirilization (46,XY DSD).[91] The biochemical diagnosis may be made by finding elevated serum 7-dehydrocholesterol (DHC) and 8-DHC with low cholesterol. These assays may be complemented by genotyping. Somewhat paradoxically, deficiency of adrenal steroid hormones is rare in SLO syndrome. The HPA axis functions normally during stress, so that corticosteroid supplementation is usually unnecessary in all but the most severe cases.[92] SLO treatment consists of a high-cholesterol diet, which may have salutary effects on behavior. Statins have also been used, sometimes combined with dietary cholesterol supplements, to reduce DHC accumulation that is thought to be neurotoxic.[93]

Other syndromes affecting adrenal development and function, such as adrenal hypoplasia congenita, IMAGE syndrome, MIRAGE syndrome, and familial glucocorticoid deficiency, are discussed in Chapter 86.

KEY POINTS

- Mineralocorticoid deficiency in the context of normal cortisol and sex steroid synthesis is most often caused by deficiency of aldosterone synthase encoded by the *CYP11B2* gene.
- The clinical manifestations of aldosterone synthase deficiency vary with age and range from hypovolemia, hyperkalemia, and dehydration in the newborn to failure to thrive in early childhood, while adults can be asymptomatic.
- Autosomal dominant mineralocorticoid excess due to glucocorticoid remediable aldosteronism is due to formation of a chimeric *CYP11B1/CYP11B2* gene that is regulated by adrenocorticotropic hormone.
- Glucocorticoid-remediable aldosteronism is characterized by early-onset hypertension with elevated aldosterone, suppressed plasma renin activity, and rapid reversal of these abnormalities following glucocorticoid administration.
- Defects in sterol delta-7-reductase encoded by the *DHCR7* gene cause Smith–Lemli–Opitz syndrome and low cholesterol with varying degrees of 46,XY undervirilization, but usually normal cortisol production.

DIFFERENTIAL DIAGNOSIS

The diagnosis of a disorder of steroid biosynthesis is generally considered in one or more of several clinical contexts. The clinician should be aware of alternative diagnoses (especially when they are equally or more common than the autosomal recessive steroidogenic defects reviewed in this chapter) and assess for them as necessary. Space does not permit a detailed discussion of differential diagnosis, and the reader is referred to the appropriate chapters for further information.

The first situation is an infant presenting with adrenal insufficiency, with hypotension, hyponatremia, and often hypoglycemia and hyperkalemia (see Chapter 93). Although CAH owing to 21-OHD is the most common genetic cause of primary adrenal insufficiency, in males X-linked adrenal hypoplasia congenital owing to NR0B1 (DAX1) mutations is at least equally common. However, the latter condition is more difficult to ascertain, because there are no elevated steroid precursors, and thus it cannot be detected by newborn screening targeting elevated 17-OHP. The clinician should always consider the possibility of an acquired cause of adrenal insufficiency such as sepsis or hemorrhage. Finally, in the absence of hyperkalemia, the possibility of secondary adrenal insufficiency should be considered, particularly in infants suffering from central nervous system insults such as head trauma or hypoxic-ischemic encephalopathy.

A second situation is the infant with atypical genitalia (Chapter 101). In a phenotypic female infant with a uterus, the most common alternative etiology to 21-OHD is mixed gonadal dysgenesis, which occurs in approximately 1:20,000 births. Phenotypic male infants with isolated hypospadias rarely have an identifiable genetic or metabolic etiology. More severely undervirilized XY males, including XY phenotypic females, most often have complete or partial androgen insensitivity, with nonvirilizing forms of congenital adrenal hyperplasia such as 17-hydroxylase deficiency occurring much less frequently.

Finally, nonvirilizing forms of CAH are often considered as etiologies for lack of development of secondary sexual characteristics or primary amenorrhea in adolescent phenotypic females (see Chapter 103). Turner syndrome is far more common than CAH in this clinical context.

KEY POINTS

- The diagnosis of a defect of adrenal steroidogenesis needs to be considered within the context of the clinical situation.
- Although congenital adrenal hyperplasia (CAH) due to 21-hydroxyase deficiency is the most common cause of primary adrenal insufficiency in children and genital atypia in the newborn, other genetic and nongenetic causes should be considered in the evaluation of these presentations.
- Nonvirilizing forms of CAH should be considered along with more common diagnoses when there is lack of development of secondary sexual characteristics or primary amenorrhea in an adolescent phenotypic female.

MEDICAL THERAPY OF CONGENITAL ADRENAL HYPERPLASIA

Glucocorticoid Therapy

The fundamental aim of therapy for disorders of steroidogenesis is to provide replacement of deficient hormones, while balancing hormone excess. Glucocorticoid therapy is the cornerstone of treatment for all forms of cortisol deficiency. The goal of glucocorticoid therapy is 2-fold: to replace deficient cortisol and diminish risk of adrenal crisis,[94] and to control ACTH-driven steroid excess.[95] Higher doses of glucocorticoid are typically needed to achieve adequate suppression of ACTH-driven androgens in the virilizing forms of CAH than doses given for cortisol replacement when all steroids are deficient. Thus, it is important to also avoid the adverse effects of glucocorticoid excess leading to short stature, obesity, osteoporosis, and an adverse metabolic profile (see later).[3,14,96] The need for glucocorticoid therapy is variable in the nonclassic forms of CAH and in POR deficiency.

Glucocorticoid in infants and children with classic CAH is usually administered as hydrocortisone 10 to 18 mg/m^2 per day divided into three doses, with lower doses (8–12 mg/m^2 per day) used for nonclassic or mild forms of CAH. Adults may receive hydrocortisone 15 to 40 mg, or rarely 60 mg/day divided into two or three doses, or receive long-acting glucocorticoids or both. It is important to use the lowest effective glucocorticoid dose to avoid the side effects of excessive dosing.

Laboratory evaluation should guide but not define management of glucocorticoid dosing. The laboratory profile in monitoring 21-OHD typically includes consistently timed blood measurements for 17-hydroxyprogesterone, androstenedione, testosterone, plasma renin activity, and electrolytes. Suggested target ranges are mildly to moderately elevated 17-hydroxyprogesterone and normal age- and sex-specific androstenedione and testosterone levels. Normal levels of 17-hydroxyprogesterone generally indicate excessive dosing of glucocorticoid. Plasma renin activity and electrolytes should be in the normal range for age. During infancy laboratory tests are performed about every 2 to 3 months, in conjunction with growth tracking and blood pressure measurements. Older children and adolescents may be monitored every 4 to 6 months, and clinically stable adults once or twice yearly. The steroid profile over time, along with blood pressure, rate of growth, and weight gain, as well as bone maturation and physical stigmata of androgen excess, are all used in medication titration.

There are several available glucocorticoid preparations. Short-acting hydrocortisone is the glucocorticoid of choice in children because of potential growth suppressive effects of longer-acting glucocorticoids.[97] The growth-suppressive effect of glucocorticoid therapy is dose-dependent and is especially observed when doses exceed 15 to 20 mg/m^2 per day during infancy and puberty.[98,99] In 2018, an immediate-release granule formulation of hydrocortisone in capsules for opening for direct oral dosing or dosing mixed with food (Infacort/Alkindi, Diurnal Limited, UK) became available in the European Union with pediatric doses (0.5, 1, 2, and 5 mg).[100] Dividing hydrocortisone 5 mg tablets is often used in the United States for pediatric dosing, but this practice is particularly problematic in the European Union and other countries, where the smallest licensed dose of hydrocortisone is 10 mg. The use of compounded hydrocortisone or liquid suspension by individual pharmacies is not recommended because of reports of variable dose accuracy in compounded preparations.[3,101,102]

Practice is highly variable in the treatment of adults. Hydrocortisone remains preferred, because it is associated with a higher bone mineral density and better metabolic and cardiovascular outcome compared with longer-acting glucocorticoid preparations.[103,104] However, due to its short half-life of 4 to 6 hours, it often needs to be given three times daily and may not adequately suppress the overnight rise of ACTH driving excess adrenal androgens in the virilizing forms of CAH and DOC in the hypertensive forms of CAH. Therefore, long-acting glucocorticoids are often used. In adults with virilizing CAH, a nighttime dose of prednisolone or prednisone can be added at bedtime.[105] A twice-daily regimen with prednisolone or prednisone (4.0–8.0 mg per day) or once- to twice-daily dose of dexamethasone (0.25–0.5 mg per day) may be used instead. Dexamethasone, in contrast to prednisolone, prednisone, or hydrocortisone, is not inactivated by placental 11β-hydroxysteroid dehydrogenase type 2. Therefore, dexamethasone should not be used in women of reproductive age who are heterosexually active, and should be avoided during pregnancy.[3] In 2011, a modified-release hydrocortisone formulation (Plenadren, Shire Services BVBA) became available in Europe. It provides immediate release in the morning and is used once daily in patients with adrenal insufficiency, with positive effects on weight, body mass index, and hemoglobin 1Ac compared with conventional hydrocortisone replacement.[106] However, Plenadren fails to control the early-morning rise in ACTH, and therefore is not used to treat disorders of steroidogenesis with ACTH-driven hormone excess such as the virilizing forms of CAH. A modified- and delayed-release preparation of hydrocortisone (Chronocort, Diurnal, UK) that mimics the circadian rhythm of cortisol release is currently in phase III clinical trials.[107,108] This formulation aims to control the overnight ACTH-driven hormone excess (see Future Directions and Novel Therapies later).

Patients with nonclassic CAH do not necessarily need glucocorticoid therapy. They are treated according to their symptoms.[3] Accordingly, children with nonclassic 21-OHD are treated if they have progressive signs and symptoms of virilization with advanced skeletal maturation. Women with nonclassic 21-OHD with signs of androgen excess can sometimes be treated with oral contraceptives or in combination with spironolactone. Glucocorticoid therapy is used for female infertility in nonclassic 21-OHD, and time to conception[109] and miscarriage rate are reduced with glucocorticoid treatment.[110,111]

Glucocorticoid therapy is also used to treat infertility in males with TARTs.[3,112] Glucocorticoid optimization and intensification can shrink TART and prevent progressive enlargement and eventual infertility; however, nonreversible fibrotic changes can occur with time. Semen cryopreservation could be offered to patients with TARTs, because irreversible testicular damage may occur.[12] Surgery can be used to treat orchialgia when large masses are present but has not been able to restore fertility.[113]

All patients with disorders of steroidogenesis who are receiving glucocorticoid therapy are at risk for increased mortality due to adrenal crisis and require glucocorticoid stress dosing for illness, trauma, and major surgery (see Adrenal Insufficiency, Chapter 93). Patients receiving glucocorticoid therapy should be educated regarding stress dosing during illness, trauma, and major surgery. Prevention of adrenal crisis is best accomplished through repeated structured patient education, and all patients should wear medical alert jewelry or have an emergency card indicating adrenal insufficiency.[114] Life-threatening adrenal crises are most often triggered by infectious illnesses[115] and are reported as the leading cause of death in patients with adrenal insufficiency due to CAH.[116,117]

Mineralocorticoid Therapy

In the salt-wasting forms of CAH, mineralocorticoid replacement in the form of fludrocortisone is given in doses ranging between 0.05 and 0.2 mg once or twice daily to achieve a plasma renin activity in the normal range. All patients with classic 21-hydroxylase have relative aldosterone insufficiency[118] and are initially given fludrocortisone, including those with the simple virilizing form. Mineralocorticoid use during childhood in patients with classic 21-OHD is associated with improved height outcome, because mineralocorticoid replacement ensures euvolemia and diminishes ACTH-driven androgen production, allowing for reduced glucocorticoid dosing.[6]

Mineralocorticoid requirements are independent of body surface area. Physiological mineralocorticoid resistance is present during infancy, requiring salt supplementation (1–2 g NaCl given in divided doses throughout the day) and higher doses of fludrocortisone. Salt supplementation may not be needed if high doses of fludrocortisone are used[119]; regardless, an increased renal sensitivity to mineralocorticoid occurs around 3 to 4 months of life requiring reduction of salt supplementation (if used) and fludrocortisone, with close monitoring to prevent hypertension. In patients with the salt-wasting forms of CAH, patients may benefit from additional salt intake during hot summer months or on days of sports activities. A seasonal increase of fludrocortisone may be warranted for extremely hot climates.[120]

Sex Steroid Replacement

Disorders of steroidogenesis that impair gonadal function (3βHSD type 2 deficiency, LCAH, cholesterol side chain cleavage deficiency, CYP17A1 deficiency, POR deficiency) require pubertal induction and sex steroid replacement. For girls, puberty is induced with low-dose estrogen given orally or transdermally. Initial doses are below those required to induce menstruation, gradually uptitrated. The addition of intermittent progesterone (as micronized progesterone for those using transdermal estrogen, or as combined oral contraceptive pills) for cyclical withdrawal bleeding is required for 46,XX females with an intact uterus. For males, short-term testosterone may be given to stimulate penile growth in childhood. Testosterone therapy is then given at the expected time of pubarche and continued during adulthood. Gonadal function and the need for sex steroid replacement are variable for the nonclassic forms of CAH that impair sex steroid synthesis.

Antihypertensive Therapy

ACTH-dependent mineralocorticoid excess occurs with CAH due to 11-OHD and CYP17A1 deficiency. Glucocorticoid treatment mitigates the effects of mineralocorticoid excess, but DOC and mineralocorticoid metabolites often persist, and additional antihypertensive therapy may be needed. Spironolactone (50–200 mg/day in one or two divided doses) blocks the mineralocorticoid receptor and is commonly used as first-line therapy. Eplerenone and calcium channel blockers can also be used.[69]

Management of Atypical Genitalia

Prenatal Therapy. Starting in the 1980s, dexamethasone was offered to pregnant women at risk of having a child with classic virilizing CAH with the aim to prevent prenatal virilization of the external genitalia in an affected 46,XX fetus.[121,122] Dexamethasone crosses the placental barrier without inactivation, reaches the fetus, and suppresses fetal adrenal androgen production. Dexamethasone treatment is effective in reducing the virilization of affected 46,XX fetuses if started early in the first trimester, but the diagnosis of CAH cannot be made until the end of the first trimester, most often with chorionic villus sampling obtained in week 10 to 11. Because CAH is autosomal recessive, the risk of having an affected girl is 1 in 8 when both parents are carriers. Therefore, with this treatment approach, seven out of eight fetuses (all boys and CAH-unaffected girls) are treated in early pregnancy with no direct benefit until prenatal testing can determine the sex and the diagnostic status, potentially creating an unfavorable risk-benefit balance. CAH-affected girls are treated until term.

Prenatal dexamethasone is no longer routinely recommended, due to unknown longer-term safety risks.[3] In follow-up studies, early prenatal dexamethasone exposure in children not affected by CAH was shown to have an effect on cognitive function, especially poor visual spatial working memory in girls.[123] Metabolic effects, such as negative effects on glucose and lipid metabolism, have been reported in young adults who received prenatal dexamethasone therapy.[124] Multiple international groups, including medical societies in the United States and Europe, have stated that prenatal dexamethasone treatment is experimental and should only be performed in centers with full disclosure of potential risks and benefits and taking part in long-term follow-up studies.[125,126]

Genital Surgery. Historically, physicians have commonly recommended genital surgery in the first year of life for atypical genitalia. In the past two decades, advocacy groups and some physicians have recommended delaying surgery so that patients can participate in decision-making. However, the psychosocial stress of not doing early surgery has not been studied. The Endocrine Society Clinical Practice Guideline and a European Expert Consensus statement recommend that parents be informed about all surgical options, including delayed surgery and observation until the child can participate in decision-making regarding surgical intervention.[3,127] Families should be educated on the known risks and benefits of having and not having surgery, as well as the complexities of gender identity and gender assignments; this often requires the support of an interdisciplinary team of experts.[128] Long-term data on outcomes in individuals who have and have not had surgery are needed to aid in decision-making.

In the virilizing forms of CAH, vaginoplasty and repair of the urogenital sinus allow for penetrative vaginal intercourse and the potential for fertility, but concerns have emerged regarding sexual function, cosmetic outcomes, and consideration of possible male gender identity, especially in fully virilized 46,XX individuals.[129] Although prenatal and postnatal exposure to androgens may influence behavior, and male-typical behavior is common among 46,XX patients with classic 21-OHD, gender dysphoria is rare, and the usual sex assignment of 46,XX patients with virilizing forms of CAH is female.[28,29] If surgery is deferred, an examination to determine whether anatomy allows for adequate menstrual flow is needed prior to puberty. Lifelong testosterone therapy would be indicated starting at puberty if there is male gender identity in a 46,XX individual with virilizing CAH. In these cases, cryopreservation of ovarian tissue should be discussed. When the diagnosis is late and the child is being raised as a boy, the option has been suggested to suppress puberty with a GnRH agonist until a choice of gender identity is made by the individual.[130] The cultural environment is an important factor in such decisions.

Surgical reconstruction of the 46,XY atypical genitalia is complex and challenging. Surgery for repair of chordee and distal hypospadias have high success rates, but proximal hypospadias repair has higher complication and reoperation rates.[131] The complications include meatal stenosis, urethral stricture, and fistula formation. If the diagnosis of a disorder of steroidogenesis is made late in a 46,XY prepubertal child raised female, puberty can be blocked until the individual's gender identity is clear. In general, gonadectomy is recommended in 46,XY patients with a female phenotype being raised as female, but the optimal timing is unknown. Although the risk of gonadal malignancy is thought to be low, early gonadal neoplastic changes were observed histologically in a 1-year-old 46,XY patient with classic LCAH.[132]

KEY POINTS

- The main goal of medical therapy is to replace deficient hormones and control adrenocorticotropic hormone-driven steroid excess.
- Short-acting hydrocortisone is the glucocorticoid of choice for disorders with cortisol deficiency, because it is associated with fewer adverse outcomes compared with long-acting glucocorticoids.
- Management of glucocorticoid therapy is based on steroid profiles as well as clinical findings of both under- and overreplacement.
- The need for glucocorticoid therapy is variable in the nonclassic forms of congenital adrenal hyperplasia and in P450 oxidoreductase deficiency.
- Both female and male patients with the hypogonadal disorders of steroidogenesis require pubertal induction and sex steroid replacement.

FUTURE DIRECTIONS AND NOVEL THERAPIES

Emerging treatments for CAH that target various aspects of steroid production are being developed (Fig. 94.5). Circadian cortisol replacement is one approach being studied. Modified- and delayed-release hydrocortisone preparations were discussed previously. Continuous subcutaneous hydrocortisone infusion mimicking cortisol circadian rhythm and delivered via an insulin pump also has shown promise, with improved disease control, improved quality-of-life, and decreased fatigue compared with similar doses administered orally.[133] Longstanding comorbidities remain to be studied with long-term use of physiologic cortisol replacement.

Strategies for reducing ACTH are being investigated as a way to control the ACTH-driven excess androgen production and ultimately allow for glucocorticoid dose reduction. A corticotropin-releasing hormone type I receptor antagonist was studied in a single-dose phase I study and achieved delayed and attenuated morning rise in ACTH and 17- hydroxyprogesterone in six of eight females with classic 21-OHD.[134] Two additional agents of this drug class are currently being studied in clinical trials in adults with classic 21-OHD (NCT03257462; NCT03687242; NCT04045145). An ACTH receptor (MC2R) antagonist[135] and a long-acting neutralizing monoclonal ACTH antibody have been tested in animal models[136] as ways to attenuate ACTH-dependent steroidogenesis.

Adrenal sex hormone-lowering agents and antagonists are being studied in prepubertal children and women receiving sex hormone replacement therapy as a way to allow for lower-dose glucocorticoid treatment in the virilizing forms of CAH. The use of an antiandrogen and aromatase inhibitor in combination with lower-dose hydrocortisone and fludrocortisone was successful in normalizing growth over 2 years in 28 prepubertal children with classic 21-OHD.[137] Abiraterone acetate, a potent inhibitor of CYP17A1, lowered androstenedione concentrations in five of six women after 6 days of treatment.[138] A study of abiraterone acetate in prepubertal children with CAH has been initiated (NCT02574910). A case report describes the use of mitotane, an adrenal enzyme inhibitor with adrenolytic properties, in the treatment of TARTs, with restoration of fertility, although potential toxic side effects limit the use of mitotane for this indication.[139] Nevanimibe (ATR-101), another inhibitor of adrenal enzyme production with potential adrenolytic properties, decreased 17-hydroxyprogesterone levels in patients with classic 21-OHD within 2 weeks of treatment in a dose-escalation study.[140] Further study of longer duration and with higher doses is needed to determine safety and efficacy.

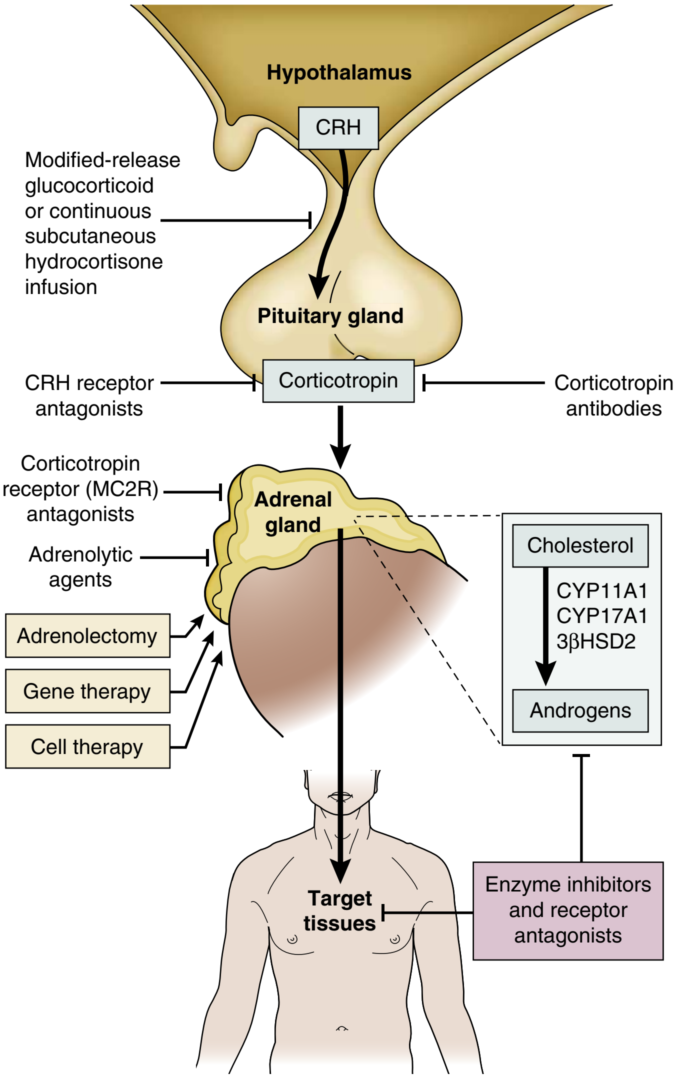

Fig. 94.5 New therapies for congenital adrenal hyperplasia. New therapeutic approaches target different aspects of the pathophysiology of congenital adrenal hyperplasia (CAH). Circadian cortisol replacement through the use of a modified-release glucocorticoid or subcutaneous hydrocortisone infusion aim to control corticotropin-driven hyperandrogenism by replacing cortisol in a physiological manner. Other approaches to reduce androgen production without chronic supraphysiological glucocorticoid exposure include corticotropin-releasing hormone receptor-1 antagonists, adrenocorticotropic hormone (corticotropin; ACTH) antibodies, adrenocorticotropic hormone receptor (MC2R) antagonists, adrenolytic agents, adrenalectomy, and pharmacological inhibition of steroidogenic enzymes or steroid receptors in the adrenal or peripheral tissues. Because CAH is a monogenic disorder, gene therapy with cell-based and gene-editing technologies may be able to restore defective steroidogenesis. CRH denotes corticotropin-releasing hormone (sometimes referred to as corticotropin-releasing factor [CRF]). (From Merke DP, Auchus RJ. Congenital adrenal hyperplasia due to 21-hydroxylase deficiency. *NEJM.* 2020;83:1258. Reprinted with permission.)

Isolated and uncontrolled proof-of-concept trials have used growth hormone, with or without GnRHa,[141] or, in two patients with classic 11-OHD CAH, an aromatase inhibitor.[142,143] In the absence of more detailed studies, routine use of growth hormone or aromatase inhibitors is also not recommended.

Surgical adrenalectomy has been used to restore fertility in women with classic CAH and for select patients with excessive virilization who cannot be successfully managed with conventional medical therapy without concomitant iatrogenic Cushing syndrome. In a metaanalysis of 48 patients with CAH who had undergone bilateral adrenalectomy, the majority of patients reported symptomatic improvement postoperatively with successful reduction of both glucocorticoid dose and androgen levels, but adverse outcomes included adrenal crisis and the development of adrenal rest tumors.[144]

Disorders of steroidogenesis are monogenic diseases that may be amenable to gene therapy. With advancements in cell-based and gene editing technologies and the increase in safety of gene therapy using recombinant adeno-associated virus vectors, the development of gene therapies for patients with CAH are underway in preclinical programs but will be of lower priority for clinical implementation than treatments for diseases (such as adrenoleukodystrophy) for which no satisfactory treatment exists. An adeno-associated virus CYP21 vector restored 21-hydroxylase activity in CAH mice for more than 15 weeks.[145] In another approach, regenerative therapies are being studied including the transformation of pluripotent stem cells to steroidogenic cells and the use of immune-isolating biomaterials for adrenal transplantation.[146]

KEY POINTS

- Novel therapies being developed for congenital adrenal hyperplasia target various aspects of steroid production and include mimicking the circadian rhythm of cortisol secretion, reducing adrenocorticotropic hormone, administering adrenal sex hormone-lowering agents and antagonists, and applying gene-modifying therapies.

CONCLUSION

Disorders of steroidogenesis are a group of rare diseases with potential mortality and high morbidity if left undiagnosed and untreated. Advances in our understanding of the genetics and pathophysiology of this spectrum of disorders has improved diagnosis and disease management, but additional advances are needed to improve outcomes. The overarching goal of therapy is to provide replacement of deficient hormones, while balancing hormone excess and reducing comorbidities. Numerous novel approaches aim to improve patient outcomes for these rare genetic diseases of adrenal steroidogenesis.
